Prognosis.—It is very difficult to state general rules of prognosis in valvular affections of the heart, as so much depends on the peculiarities of each case. There are, nevertheless, certain broad rules. As regards origin, rheumatic inflammation is less serious than degenerative change, which occurs later in life, and is necessarily progressive. Accidental rupture is the gravest form of origin. The valve affected is also a prognostic element; but any attempt to arrange cases in order according to the seat of the valvular defect, must be open to many exceptions that it must not be too much trusted. Speaking generally, however, tricuspid lesions are gravest, mitral less so, and aortic—especially aortic stenosis—probably least so. When the heart fails, and *asystole* supervenes, the prognosis is worse, however, in aortic cases than in mitral.

Aortic cases are often free for years from any grave symptoms. When the murmur is conducted to the left apex, the prognosis is more favourable, as, the aortic segment affected being non-coronary, the muscle of the heart is not robbed of its blood. The presence of the second sound

over the carotids is favourable. The pulsating also affords valuable aid in prognosis, as it gives, by the size of the diastolic wave and the obliquity of the line of descent, a rough measure of the amount of insufficiency. There is much more risk of sudden death in aortic cases than in mitral.

In mitral lesions the dangers arise from the pulmonary complications; embolism is more common than in aortic affections. Mitral cases can be rescued from *asystole* more commonly, and die of advanced cardiac cachexia, generally with dropsy. Under favourable conditions of life, requiring little physical exercise and causing no emotional excitement, both forms of mitral disease are compatible with many years of life. When they are conjoined, the prognosis is more unfavourable. In cases of sudden insufficiency, produced by rupture of the valve-curtains or of the tendinous cords, death may occur very rapidly from the disturbance of the circulation.

The whole question of prognosis turns principally on the state of the myocardium. So long as this is sound, compensation may be maintained; the moment degeneration sets in, *asystole* and all its evil train of symptoms come on. Thus *asystole* coming on gradually, without any previous overstrain of the heart, is always most grave. Each successive attack becomes graver, and the visceral congestions which accompany it more stubborn. Albuminuria is a good index of the gravity of the congestion, and is serious in proportion to the frequency with which it has occurred. In some cases a copious flow of limpid urine is a very grave symptom. Dropsy of the extremities, and of the cavities more especially, is bad, as indicating failure in the peripheral circulation. Next to the cardiac muscle, the state of the peripheral vessels is most important; thus, atheroma and other conditions, such as febrile attacks, add to the danger by interfering with the circulation. The general nutrition of the patient suffering from valvular disease also enters into the prognostic problem. There is a cachexia proper to the end of heart-cases, which is due to the gradual deterioration of the nutritive fluids by the long-continued visceral congestions which hinder assimilation and excretion. Blood is less perfectly made and less perfectly purified; hence the steady deterioration of cardiac cachexia, which is always of evil import as regards duration of life. Valvular diseases are, however, in numerous instances compatible with many years of life. In some the healthy expectation of life may be attained; and, in many, years of comparatively active life are enjoyed. In the poor, the prognosis, as to duration, is not favourable; but in the well-to-do, all observers see many cases extending over a great number of years.

Treatment.—Valvular affections of the heart, whether the result of rheumatic inflammation or of degenerative change, are, as a rule, incurable. Some few cases of rheumatic origin lose the signs of valvular disease, and are practically restored by the after-processes (for example, contraction) in the inflamed valve; and some few cases also of mitral insufficiency, associated with dilated left ventricle, are cured by treatment. These exceptions are, however, few; and as we cannot repair the valve-mischief, in the vast majority of cases,

ent treatment must be directed to aid the compensatory hypertrophy, and to check the development of the consequences of the defect. The maintenance of the nutrition of the substance of the heart is, therefore, the main object of treatment; just as the state of the nutrition of the heart is the key to the prognosis. On this account the general regimen of heart-cases is very important.

General regimen.—The diet should in all cases of valvular disease of the heart be unstimulating but sustaining, consisting of a good proportion of albuminous food (underdone meat, eggs, and fish), with wine in moderate quantity, and some chalybeate water. There should be no unnecessary excitement of the heart, either by exercise or emotion. All athletics and violent efforts should be avoided by the young, especially in mitral cases. In aortic cases, steady exercise without strain is beneficial. The residence should be so situated as to avoid the necessity of exertion, sudden changes of temperature, cold, and damp. The chief object of the regimen should be to prevent anemia, hence plenty of fresh air is essential. Tobacco is injurious. In early life over-exertion and exposure to cold—in adult life, emotional, sensual, and dietetic excesses, are the chief dangers. The propriety of marriage must be considered in each case on its merits. Women, as a rule, should not marry; when affected with mitral disease they are often barren. To men marriage is more generally permissible.

Medicinal treatment.—The therapeutics vary according to the stage of the cardiac disease. The mechanical defect of a valve first makes itself felt by palpitation and precordial pain; these symptoms pass away when compensation is effected, but till then require treatment. In cases of mitral disease, tincture of digitalis (mx doses) relieves the palpitation; chloric ether is also a useful adjunct. In aortic cases, ether, diffusible stimulants, small doses of opium and belladonna, with the local application of belladonna to the precordial region, are valuable remedies.

The precordial pain, mostly retro-sternal, may, when severe, require a few leeches or cupping, but generally yields to mild counter-irritants, such as turpentine or mustard. Internally, the bromides are useful; when the pain occurs paroxysmally, ethereal preparations and ammonia act well.

When the compensatory changes in the heart are effected, the palpitation and pain decline, and the chief indication is to keep up the nutrition of the heart by the hygienic rules above given, and by the administration of preparations of steel, combined with arsenic, strychnia, quinine, and mineral acids. Chalybeate waters are also useful adjuvants. The syrup, infusion, and tincture of the prunus virginica are preparations of value in some cases after the use of digitalis. The secretions should be carefully watched, and the bowels opened freely every day, so as to avoid straining, and to relieve the portal circulation. The quantity of urine should be daily noticed, as it is a capital index of the state of arterial tension. Patients in whom the most perfect compensation exists, are, nevertheless, in a state of imminent

trouble, for an exaggeration of a physiological act or emotion may disturb the unstable equilibrium of their health. In most cases the compensation breaks down sooner or later; and then begin the symptoms depending on pulmonary congestion and general visceral engorgement, with the consequent impoverishment of the blood. Dyspnoea marks the beginning of these troubles; anemia and dropsy the close. The pulmonary congestion soon manifests itself by bronchial catarrh, which requires expectorants in various combinations, while friction, poultices, and counter-irritation are applied to the chest-walls. In capillary bronchitis with rapid pulmonary congestion, it is sometimes necessary to bleed from the arm to relieve the over-distended cavities of the right side of the heart. Nauseating doses of ipecacuanha, or actual emetics of sulphate of zinc, are sometimes very useful.

For the general visceral congestions our chief remedies are, firstly, diuretics; and, failing these, hydragogue cathartics. Of diuretics, the salts of potash, squilla, broom, chimaphila, spirits of nitrous ether, juniper and digitalis are the most useful. The hydragogue cathartics, which relieve the over-distended portal vessels primarily, and the general circulation secondarily, are also most valuable; of these the compound powders of scammony and jalap in 20- to 40-grain doses; bitartrate of potash in electuary, 5j to 3ij, every morning; sulphate of magnesia; pilula scammonii composita; elaterium; senna; and gamboge are the most trustworthy. By the judicious use of an occasional purgative, and the administration of a suitable diuretic, aided by cupping, poultices, and sometimes a small blister over the loins, combined with rest and stimulants, the worst cases of dropsy from cardiac failure are often saved.

For the dyspnoea and the insomnia, two of the worst symptoms, we have a remedy of great power in the subcutaneous injection of morphia in doses of one-sixth of a grain upwards. This remedy acts often like a charm, and may be used even in the worst cases of both mitral and aortic disease, but always with caution. Albumen in the urine does not necessarily contraindicate its use. In some cases chloral and bromide of potassium, alone or in combination, are valuable remedies for the insomnia, but they must be given cautiously. The bromides may also be prescribed with other sedatives for the dyspnoea. The compressed air bath in some cases also relieves the last symptom.

Dropsy, like the visceral congestions with which it is associated, requires the use of diuretics and hydragogue cathartics. When these fail, the swollen limbs may be sometimes punctured with benefit. Continued friction of the limbs, by stimulating the vessels, will often cause considerable anasarca to disappear. The drug on which main reliance must be placed when general dropsy supervenes is digitalis. This remedy has so great a share in the therapeutics of heart-disease, and a knowledge of its action is so important, that it must be discussed separately and last. Whatever views may be held as to the physiological action of digitalis, its greatest triumphs are seen clinically in the treatment of valvular diseases, when cyanosis, distended jugu-

lars, dyspnoea, congested viscera, dropsical limbs, scanty urine, tumultuous heart-action, and quick, irregular, and failing pulse, indicate *asthymia*. This assemblage of symptoms is mostly seen in mitral cases, and it is precisely in this class that the drug is most valuable. Under its use 'the pulse grows in force, fulness, and regularity; the arterial tension rises; the pulmonary congestion diminishes; the kidneys, before inactive, wake up to their work; and the advancing dropsy recognises its master and beats a sullen retreat.' In mitral stenosis these good results are due not only to the increased vigour given by the drug to the contractile power of the heart, but also to the fact that by its slowing action the diastolic period of each revolution is lengthened, and the time thus increased during which the over-full auricle can force its contents through the narrowed mitral orifice into the left ventricle. Digitalis here not only obtains a better filling of the ventricle, but a more effective discharge of its contents when filled, and thus, under its use, beat by beat, the general and pulmonary venous congestion is relieved. In mitral insufficiency it is almost equally potent. In both forms certain of its good effects would seem to be due to some influence, probably through the pneumogastric nerves, in producing contraction of the pulmonary blood-vessels. It is perhaps this property which makes it valuable in pulmonary hemorrhages independent of heart-disease.

In aortic valvular diseases digitalis is not so valuable a remedy. In these cases the assemblage of symptoms mentioned above is not met with, except sometimes in the later stages, when the mitral valve is secondarily affected, and the case is not one of pure aortic disease. In these compound cases the drug is valuable, especially in combination with stimulants. In aortic insufficiency alone, the slowing action of the digitalis produces evil by increasing the length of the diastolic period of each revolution, during which the regurgitation takes place. The force it may give to the systole is no gain in the face of this slowing action, inasmuch as the aortic recoil gains in the same proportion as the ventricular systole, and thus forces blood back into the ventricle with increased vigour during the lengthened diastole. It is important in aortic insufficiency to encourage the frequency of the cardiac action; hence those cases are so constantly the better for bodily activity; and so, when the toning effects of digitalis are required, it should always be given in combination with ether and ammonia, to keep up quick action of the heart, and to prevent the vertigo and syncope which may otherwise occur. When there is excessive hypertrophy in cases of aortic insufficiency, digitalis is useful sometimes in quieting palpitation, reducing excessive frequency, and lessening headache and vascular excitement. Caffeine and veratrum viride also relieve these symptoms, but a few drops of nitrite of amyl inhaled from cotton-wool are more rapidly and surely beneficial than any other remedy. In aortic stenosis digitalis is rarely required. The simple mode of compensation makes these cases require little treatment. Digitalis is sometimes useful in combination with stimulants to give vigour to the myocardium, and check the tendency to dilatation. If it slows

the action of the heart notably, its effect becomes hurtful. Nux vomica often prevents this.

In combined valvular lesions, the predominant lesion must be the guide in the use of digitalis; but it may be given advantageously whenever the general signs of venous stasis are present. The diuretic power of the drug is one of the best tests of its beneficial action. Relying on this test, the writer often gives digitalis for weeks, nay, months at a time, and obtains improvement in the nutrition of the heart which lasts long after its discontinuance. Digitalis effects this improvement by increasing the vigour of the coronary circulation, and thus builds up new heart-muscle to compensate a valvular defect.

The preparations of digitalis which may be used are, the powder in $\frac{1}{2}$ -to 1-grain; the tincture in $\text{m}\times$ to xxx ; and the infusion in 3j to 3vj doses. As a diuretic in cases of dropsy, the old combination of squill, digitalis, and blue pill is invaluable.

HEART, Valves of. Aneurism of.—**DEFINITION.**—A valvular aneurism is a circumscribed pouching or acculation of one of the valve-segments.

DESCRIPTION.—Two forms of aneurism of the valves of the heart are met with. In the one, the whole thickness of the valve is dilated by the blood-pressure to form the pouch; in the other, one of the lamellae being ulcerated by endocarditis, the blood pushes the remaining lamella before it to form a sac. The second form, which is sometimes called 'acute valvular aneurism,' occurs most commonly in ulcerative endocarditis. Valvular aneurisms vary in size, from a pea up to a pigeon's egg. The orifice is almost invariably towards the greatest blood-pressure—those on the mitral valve opening towards the left ventricle, those on the aortic valves towards the aorta. They are usually rounded in shape, but may have irregular prolongations between the lamellae of the valves. Valvular aneurisms are sometimes multiple. The valves of the right side of the heart are seldom affected. The mitral valves are the seat of the larger aneurisms, and are twice as often aneurismal as the aortic valves.

Valvular aneurisms terminate commonly by early rupture, giving rise to perforation and consequent insufficiency of the valve, and often leading to considerable laceration. Rupture occurs more rapidly in aneurism of the aortic valves. Mitral aneurisms occasionally become chronic, and filled with coagulum; and aortic valve aneurism may also be found filled with solid clot.

SYMPTOMS.—The clinical history of this form of disease is defective. When seated on the mitral valve, aneurisms usually give rise to no signs until the perforation and laceration of the valve suddenly develop the murmur of mitral insufficiency. An aneurism of one of the aortic segments causes a soft systolic murmur over the valves, which one day, as the sac ruptures, is supplemented by the murmur, and accompanied by the symptoms of aortic insufficiency. The phenomena of this accident are similar to those of sudden rupture of an aortic valve.

HEART. Wounds of.—*SYNON.*: *Fr. Blessure du Cœur*; *Ger. Herzwunden*.

The subject of wounds and other injuries of the heart belongs more properly to the domain of Surgery, but being in several respects of much medical interest, it requires to be briefly discussed here.

ÆTHIOLOGY AND ANATOMICAL CHARACTERS.—Wounds of the heart may be punctured, incised, or lacerated; and inflicted with a variety of weapons or other sharp bodies, as well as by projectiles, especially bullets. Traumatic ruptures and contusions form another considerable class of injuries of the heart, which chiefly result from falls, crushing accidents (for example, being 'run over'), and blows. Injuries of the heart due to the entrance of foreign bodies, such as a needle or a bone, may be inflicted in some rare cases from the interior of the œsophagus or stomach; the most remarkable case of this kind being one of wound of the pericardium from behind by the point of a sword which a juggler had attempted to 'swallow.'

Post mortem, the chest-wall generally presents evidence of the wound that has been inflicted. The pericardium rarely escapes injury; its sac is found to contain blood in recent cases, or effused lymph or pus when life has been preserved for a few days or more. The walls of the heart at the seat of injury present different appearances, according to the precise nature of the lesion. Punctured and incised wounds may be of all sizes; take either a direct or an oblique direction through the muscular fibres; and are generally penetrating. Bullet-wounds cut away a portion of the heart, whether at the borders or from the thickness of the organ. Traumatic ruptures present special characters (*see HEART, Rupture of*). In all the varieties of injury of the heart, the wound is found plugged with blood-clot, the edges being either infiltrated or ecchymosed and torn. In cases that do not prove rapidly fatal, the usual signs of inflammation, or healing, and even cicatrization, are found in the heart; or aneurism of the cardiac walls may be developed as a result of the latter. The valves and their appendages are frequently incised or otherwise injured. In some cases a portion of the weapon, projectile, or foreign body may be found in the heart. The ventricles—and especially the right ventricle—are the parts of the heart most commonly injured. The great vessels, lungs, and the arteries of the chest-wall, may also be wounded in different instances.

From these appearances it is evident that wounds of the heart may prove rapidly fatal by loss of blood, by shock, or by compression of the heart resulting from hæmorrhage into the pericardium; whilst, at a later stage, pericarditis, myocarditis, and secondary hæmorrhage may be expected to supervene.

SYMPTOMS, CAUSES, AND TERMINATIONS.—In about one-third of recorded cases of injury of the heart, either death is immediate—fainting, convulsions, and the other symptoms of syncope, as well as those of shock, being the prominent phenomena, along with external hæmorrhage; or the patient drops dead after a few moments, during which time he may have undergone considerable anæmia. In a second class of cases, the

symptoms of syncope or of shock occur immediately, but death does not at once ensue. The patient then lies in a state either of unconsciousness or of complete prostration. In the latter event he complains of a sense of great debility, precordial oppression, dyspnoea, and suffocation; the surface is cold, pallid, and trembling; vomiting may occur; and there is usually hæmorrhage from the region of the heart. Death occurs after minutes or hours, either from exhaustion due chiefly to continued or repeated loss of blood, or from compression of the heart. In a third series of cases, the course is more protracted. The patient, after suffering from the symptoms just enumerated, but in a less degree, passes through the various phases of constitutional disturbance commonly observed in severe wounds, complicated, however, with pericarditis, myocarditis, and repeated hæmorrhage; and dies of exhaustion after an illness of weeks or months. Lastly, in a small proportion of cases, the patient survives the various accidents and complications just described, and the wound of the heart heals; but it sometimes happens that symptoms of aneurism of the cardiac walls, or of incompetence of the valvular apparatus, are developed as the result of the lesion.

DIAGNOSIS.—Wounds of the heart can usually be diagnosed without difficulty by the situation of the external injury, and the severity of the symptoms. Similar symptoms may, however, follow injuries of the great vessels in the neighbourhood of the heart, or of the arteries of the walls of the chest, if the hæmorrhage be profuse; but unless there be almost complete certainty that a vessel within reach is the only seat of the bleeding, the diagnosis should be left undecided, and all dangerous interference avoided.

PROGNOSIS.—Injury of the heart is generally to be regarded as certain to end in death; but it should not be forgotten that as many as 12 per cent. of recorded cases are said to have recovered. Some very remarkable instances have occurred of recovery after very severe injury to this organ; for example, a case in which a bullet was lodged in the substance of the heart for twenty years. (*See British Medical Journal*, March 23, 1867.) The prognosis may be broadly estimated by the severity of the immediate symptoms. Traumatic rupture of the heart is said to have invariably proved fatal.

TREATMENT.—In wounds of the heart, the hæmorrhage must be at once arrested by the usual surgical means; immediate death must be prevented by cautious stimulation; and the patient must be kept in such a condition that, whilst life is preserved, the danger of inflammatory reaction in the region of the heart, and of fresh hæmorrhage, is reduced to a minimum. It is on this account that restorative measures are to be guardedly employed at first, and resorted to in the further progress of the case only when urgently indicated. Absolute rest of body and mind is indispensable. Nerve and cardiac sedatives, such as bromide of potassium, morphia, chloralhydrate, and belladonna, may be of great service when used with judgment.

J. MITCHELL BRUCE.

HEARTBURN.—*SYNON.*: Cardialgia.—

Heartburn is a hot or scalding sensation, usually referred to the cardiac orifice of the stomach, but in some cases diffused over the whole abdomen. It is frequently accompanied by eructations of a very acid character; and the fluid rejected from the stomach produces a sensation of scalding in the throat and œsophagus.

Ætiology.—Heartburn exists in a very marked degree in dilatation of the stomach, being produced by the decomposition of indigestible food retained in this organ. It constantly accompanies chronic enterhæmorrhægia, the retained mucus enclosing particles of food in a state of decomposition, which set up fermentation in the materials of each meal as soon as it is swallowed. Heartburn is common in the later period of pregnancy, probably because the stomach is so displaced that it is unable properly to expel its contents.

Treatment.—This sensation is best treated by antacids, such as chalk, magnesia, alkalies, and alkaline waters. In some cases powdered charcoal relieves it. The diet for persons that suffer severely from heartburn requires careful regulation. All articles of food containing much fat, sugar, or starch, should be avoided. The use of tobacco should be interdicted, the writer has frequently seen obstinate cases kept up by smoking and chewing. Alcoholic stimulants should be used very sparingly, the least likely to do harm being brandy mixed with Vichy or potass water. The writer has obtained good results by substituting gluten bread for the ordinary baker's bread, and where this could not be taken, has found advantage from the use of aerated or some other kind of unfermented bread. Some women who suffer severely from heartburn when pregnant find relief from eating lettuce.

S. FENWICK.

HEART-CLOTS. See HEART, Thrombosis of.

HEAT, Ætiology of. See DISEASE, Causes of; and the following article.

HEAT, Effects of Severe or Extreme.—(A) Constitutional Effects of Severe Heat applied generally.—The constitutional or general effects of exposure of the whole body to high temperatures vary with the source and degree of heat, the slowness or rapidity of transition from lower temperatures, and the length of exposure; as well as with the age, constitution, habit and health of the body; and they are liable to be more or less modified or obscured by various concomitant circumstances and conditions, such as the barometric pressure, the hygrometric state, and the purity or impurity of the atmosphere.

The range of temperature within the limits of which life can be maintained appears to be greater in the case of man than in that of most of the lower animals, in virtue of greater power of accommodation to external influences, without undue elevation or lowering of the temperature of the body. But in every case any such combination of external circumstances as causes the temperature of the body to rise 10° to 15° above the normal standard speedily proves fatal.

Artificial heat.—Numerous observations and

experiments show that in dry air exposure to very high temperatures can be borne, during periods varying with circumstances, without danger or even serious inconvenience, the temperature of the body being kept down within safe limits by evaporation from the surface and from the lungs. Thus, in Dobson's experiments, a temperature of 310° was sustained during twenty minutes; Blagden exposed himself during eight minutes to a temperature of 380° ; Chantrey's workmen were accustomed to enter a drying oven in which the thermometer stood at 340° ; and Chabert, the 'Fire King,' is said to have frequently exposed himself to a temperature of from 400° to 600° . Glass-workers, metal-founders, gas-stokers, engineers in steamboats—especially in the tropics—bakers' oven-builders, and others constantly carry on their work in temperatures of from 120° to 160° , or even higher, to say nothing of the blasts of radiant heat to which some are from time to time exposed. In moist air, evaporation from the surface and its cooling influence being diminished or prevented, much lower temperatures speedily become insupportable. Berger was unable to remain in a vapour bath the temperature of which had risen from 106° to 120° , although he had easily borne a temperature of 230° in dry air for five minutes.

The effects upon the temperature of the body, pulse, respiration, &c., recorded by previous observers, are, in the main, supported by the recent careful experiments of Dr. Fleming in the Turkish bath.¹ He found that exposure during an hour to a temperature commencing at 170° and lowered to about 130° , caused the temperature of his body (taken by a specially devised thermometer in the mouth), to rise rapidly during the first ten minutes from a normal average of 97.65° to 99.2° (a rise of 1.55°); and then more slowly until the end of fifty minutes, when the highest point 101.3° (a rise of 3.7°) was reached. His pulse rose during the first ten minutes from 78 to 91 beats in the minute, and like the temperature attained its maximum—116, at the end of fifty minutes. His breathing first diminished in rapidity from 22.5 to 20.8, and then increased to 25.4 in actual rapidity, but maintained a diminished ratio to the pulse. The arterial tension seemed to be increased by the greater rapidity of the heart's action, combined with the gorged state of the capillary circulation. The quantity of material eliminated during the hour amounted to forty-four ounces. The proportion of chlorides in the urine passed after the bath (3.65 in the 1,000) was little more than half that in the sweat (8.05) collected during the bath, and much less than in the urine previously passed (6.68). The proportion of urea in the urine was slightly increased, and the sweat contained 1.65 in the 1,000.

The effects felt by those exposed to great heat vary with the temperature, the length of exposure, and the collateral circumstances. A sensation of warmth, at first agreeable, is succeeded by one of oppressive and then painful heat, until this is again relieved by the establishment of copious evaporation from the surface. Flaming

¹ *Journal of Anatomy and Physiology*, July 1879.

stimulation, and some degree of excitement of the nervous and muscular systems, are quickly followed by languor, lassitude, listlessness, feelings of exhaustion, indisposition to mental effort or muscular exertion, dizziness, tendency to sleep, faintness and unconsciousness, sometimes accompanied or preceded by convulsions. If relief is not afforded death ensues. If timely relief is afforded, more or less speedy and complete recovery may be brought about.

Symptoms and conditions closely or exactly resembling those of sunstroke, may be produced by exposure to an artificially heated atmosphere, or to blasts of radiant heat from fires or furnaces. If the symptoms have been severe and persistent, or if the sufferer has been exposed to repeated attacks, permanent damage to the health, and especially to the nervous system, almost certainly results, in spite of apparent temporary recovery. In many cases general debility and deterioration, in some cardiac troubles, and in others insanity, have been recorded as the persistent after effects.

Bernard, Delaroché, and others have shown that animals exposed to temperatures of from 130° or lower, to 150° and upwards, quickly die.

The *post mortem* examination of animals so killed showed that the heart had entirely ceased to beat at the moment of death, and that neither it nor the muscular coat of the intestines could by any means be stimulated to contract again. The muscular fibres of the heart examined microscopically appeared rigid and coagulated (Kühne and Ranvier). Further, the blood in both arteries and veins was dark coloured. *Rigor mortis* set in very early, and general decomposition very speedily commenced. It would thus appear that (apart from sudden shock to the system generally) the cause of death from exposure to high temperatures is to be found in the effect produced on the muscular system of organic life, and especially on the heart. The cardiac myosin coagulates at 115° , and at a temperature considerably short of this its condition must be seriously affected.

ANATOMICAL CHARACTERS.—The *post mortem* appearances met with in the human subject in cases in which death has been attributed to the general effects of heat have not been uniform. The following case, however, recorded by C. Speckl¹ is noteworthy. A girl, set fourteen, the subject of chronic disease of many of her joints, was, on the advice of a quack, wrapped in a sheepskin warm from the carcass, laid in bed, surrounded with hot leaves fresh from the oven, and covered by the clothes. In about an hour she complained of pains, especially in one arm. She soon fell asleep. It was noticed that her chest rose and fell strongly. She perspired freely, and the sweat was frequently wiped off. She became very pale, and about three hours after the commencement of the treatment she expired, without having recovered, or at any rate manifested, consciousness. On *post mortem* examination the next day (the weather being cool and dry) advanced decomposition was found; the blood being black and fluid, and the blood-vessels, cavities, and tissues generally full of gas. The heat of leaves fresh from the oven, such as

were put round the child, was found to be 185° .

TREATMENT.—The *immediate* treatment to be adopted in the case of those suffering from exposure of the whole body to heat consists essentially in removal into a cooler atmosphere, quiet rest in the recumbent position, fanning, cool or even cold affusions or sponging, especially over the head and spine—the effect, however, being carefully watched; and the administration of cool or lukewarm fluid in small quantity at a time, with some stimulant. Copious draughts of cold water in a highly heated state of body are liable to give rise to dangerous or even fatal results. Bleeding is not to be recommended.

The *after treatment* must be conducted on general principles, and determined by the condition of the patient, and the indications afforded in the particular case.

Climatic and Solar Heat.—The effects of climatic heat experienced on transition from temperate to tropical regions are as follows. — 1st. The average temperature of the body rises 5° to 1° according to Davy and Crombie, or to a somewhat greater extent according to others. The daily fluctuations of bodily temperature in health in India correspond to those in England. The normal temperature of native Indians is about half a degree higher than that of Europeans (Crombie). 2nd. The pulse is quickened according to most observers, but Rattray says this is incorrect. 3rd. The breathing becomes slower and less deep, falling from about sixteen to about twelve or thirteen per minute. Less carbonic acid and less water are thus exhaled. 4th. The skin acts much more freely, its excretion being increased by about 24 per cent. (Rattray). The continued hyperæmia and over action of the skin, however, are liable to be followed by congestion and obstruction of the sweat follicles, giving rise to 'prickly heat'. 5th. The urine is diminished in quantity, and in amount of urea and chlorides. The experiments of Bocher (confirmed by those of Forbes Watson) showed a constant relation between the temperature, and the urea and chloride of sodium got rid of by the kidneys. As the temperature rose from 50° to 70° an increase was found, but with a further rise from 70° to 90° an almost equally constant diminution occurred. 6th. The appetite, especially for animal food, is diminished, and the digestive powers seem lowered. 7th. Lassitude, languor, want of vigour, indisposition to exertion, and a sense of exhaustion of mind and body are experienced in degrees varying with circumstances, the depressing effects being most felt when the heat is not only great but continuous day and night, and when the atmosphere is dense.

The effects of the radiant heat of the sun, as distinguished from those of atmospheric heat, are not well made out. It would appear probable, however, that a physiological effect adverse to perspiration is produced by the direct rays (Faukes), and that thus, as well as from rapid evaporation, the skin gets dry and becomes liable to certain structural changes, such as the formation of pigment, &c.

Exposure to the direct rays of the sun, or to great or continued heat in the shade, especially

¹ *Verh. d. Naturh. Ges. für gerichtliche Medicin*, 1874, p. 242.

under unfavourable atmospheric and general conditions, may give rise to heat-fever (Causa), heat-apoplexy, or one or other of the forms of sunstroke. See SUNSTROKE.

(B) **Local Effects of Severe Heat: Burns and Scalds**—The local effects of heat vary with the degree, the length of exposure, the medium of application, and the part acted upon. Burns result from 'dry,' Scalds from 'moist' heat.

SYMPTOMS—A comparatively slight degree of heat causes vascular turgescence, redness, tingling, pain, and tenderness, which soon subside. Disquamation of the epidermis may follow, but no permanent trace of injury is left. A higher degree causes severe burning pain, and great redness of surface, followed by effusion of serum beneath the cuticle (vesication). Complete restoration without scar is usually effected. Still higher degrees of heat or longer exposure cause intense pain, and immediate destruction, or consecutive destructive inflammation, of the true skin to a greater or less depth. Sloughing and supuration follow, and permanent scarring results. Violent heat and prolonged exposure cause complete disintegration and charring of the structures especially acted upon, followed by destructive inflammation and sloughing of others to a still greater depth and extent. Loss of parts and more or less serious deformity and scarring necessarily result. The separation of sloughs, and the processes of repair after severe burns, take place slowly; and as a rule the patient suffers much more acutely, and during a much longer period, than after other forms of injury involving equally extensive destruction of tissue.

The constitutional effects of burns and scalds vary with the superficial extent and situation, rather than with the depth of the injury. Thus an extensive burn or scald over the abdomen affecting only the skin is much more likely to prove fatal than a deep burn of one of the extremities, penetrating even to the bone, but of comparatively small superficial area. If more than half the surface of the body is affected the sufferer rarely recovers.

Death may result from shock to the system, either immediately on receipt of the injury, or after a period of from two or three to forty-eight hours or more. During this time the sufferer remains in a state of collapse or prostration, with pallor of complexion, lowness of temperature, coolness of breath, small or imperceptible pulse, dryness of tongue and mouth, and sometimes delirium, rigors, or convulsions. In such cases, *post-mortem* examination shows only congestion of the vessels, and especially of the brain. In some instances, characterised by painfully laboured and frequent efforts at respiration, tumultuous, irregular, feeble and very frequent action of the heart, and great precordial distress, death would appear to be due to cardiac thrombosis, rather than to simple nervous shock (Brown). In many severe cases the blood has been found on microscopical examination altered in appearance, the red corpuscles being separated into 'numerous little bits' (Ponfick and Schmidt). And it is readily conceivable that such destruction of corpuscles may give rise to severe symptoms, or even cause death.

In about forty-eight hours, more or less, if

the immediate effects of the injury have been survived, the stage of reaction and inflammation sets in. The patient revives, and some degree of general pyrexia becomes manifest. The pulse becomes quicker and fuller; the temperature rises; and the burnt part begins to discharge pus, usually of an offensive odour. Thirst, with dry red tongue, want of appetite, vomiting and constipation, followed by diarrhoea—sometimes with blood in the evacuations—are commonly experienced during the ensuing period and inflammation of internal parts often occurs, although the special signs and symptoms afforded may be obscure. The pleurae and lungs, the peritoneum, and the gastro-intestinal mucous membrane (particularly that of the duodenum) are especially liable to be affected. Evidence of inflammation of one or more of these parts, and not uncommonly of ulceration of the duodenum, is afforded on *post mortem* examination in cases in which death has occurred during this period. It has been suggested that capillary embolism, from the presence of disintegrated blood in the vessels, may cause in some cases the lesions of the internal organs (Brown).

In the course of about a fortnight after the injury, as a general rule, the sloughs will have separated, the acute symptoms will have subsided, and granulation and suppuration will have been established. But a low form of chronic inflammatory mischief in the internal organs may still be going on, and lead to fatal result, or the patient may sink, worn out by suffering, and exhausted by the profuse discharge from the suppurating surface, or by persistent diarrhoea, accompanied or not by blood in the motions. Sometimes the kidneys are affected, and blood or bloody excreta may be found in the urine. Pyæmia, erysipelas, or tetanus may occur and cause death, but there would not appear to be any special liability to those diseases after burns or scalds.

TREATMENT—Local treatment—Slight superficial burns of small extent require little in the way of treatment. Immersion in cold water according to some in hot water according to others, or exposure before the fire, affords the readiest means of obtaining immediate relief. Afterwards the part may be covered with flour, starch, oxide of zinc, bismuth, or collodion, and wrapped round with cotton-wool to protect it from the air and from accidental irritation. In cases in which there is vesication, the blisters should be pricked, the serum evacuated, and the cuticle left to form a natural protective covering, which may be advantageously strengthened and kept in position by a layer of collodion. But the punctures should be left open. Lint soaked in oil, or smeared with vaseline or some such material, should be applied, and the whole covered with cotton-wool. A mixture of chalk or whiting and vinegar, of the consistence of thick cream, is said to form an excellent application in such cases, speedily relieving pain, and helping to constitute a good protective covering.

Severe and extensive burns and scalds demand in their treatment the most careful management, and the greatest possible patience, gentleness, and firmness; for even if life be preserved, the most pitiable disfigurements and

deformities are liable to result from cicatricial contractions, unless proper preventive measures are perseveringly carried out. So soon as may be after the injury, the clothes should be removed from the patient with the greatest care—being cut away piecemeal if needful, and not removed in such way as to tear off epidermis or scorched or charred parts. The whole burnt surface should then be covered as quickly as possible with the dressing considered best, and enveloped in thick layers of cotton-wool lightly landaged on. Different dressings have been advocated from time to time, but probably there is none better, or more generally and readily applicable in hospital practice at any rate, than Carron oil (a mixture of equal parts of linseed oil and lime-water). The addition of a little carbolic acid is advantageous. A less disagreeable application may be made by substituting olive or almond oil for linseed oil. White lead, putty made thin by addition of oil, calamine ointment, carbolic oil, solution of carbonate of soda, carbolic lotion, flour, and starch, are among the other materials that have been recommended. Whatever the material selected, it should be slightly warmed and applied very thickly spread on broad strips of lint in such way as to facilitate future dressing bit by bit, and so as to avoid extensive exposure of raw surface. The first dressing should be allowed to remain undisturbed as long as possible—until, indeed, the offensiveness of the discharge, or the discomfort of the patient, indicates the necessity for its removal. The earlier dressings, however gently carried out, occasion so much suffering to the patient that—in the case of children especially—it is often desirable to administer chloroform. Poultices are sometimes useful in aiding the separation of sloughs. Any needful washing or cleansing is best done by aid of the steam spray-producer, a weak solution of carbolic acid or of *Lerax* being used. When suppuration is established, and the surface clean, the application may be varied according to the indications afforded. Calamine or zinc or lead ointment, with or without the addition of some anodyne; and lotions of lead, morphia, and glycerine, or of sulphate of zinc, are amongst those commonly employed. Iodoform, with extract of hemlock and spermaceti ointment, has been strongly recommended as tending to soothe pain, to deodorise the discharge, and favour healing. Exuberant granulations may be treated with nitrate of silver in solution, or by the application of the solid stick. When the granulating surface is in a healthy state, cicatrization may be very materially expedited by skin-grafting.

During cicatrization, and even for some time afterwards, it is of the greatest importance to keep all parts in such position as that there shall be as little deformity as possible from growing together of surfaces, and contraction of scars. This is to be effected or attempted by position, by mechanical apparatus, and by the application of strips of adhesive plaster and bandages in manner determined by the circumstances and conditions in each particular case.

Constitutional treatment.—In the early stages, alcoholic stimulants, or ammonia, and external warmth are especially requisite, and such light

nourishment as can be taken. Opium or other anodynes, as chloral or bromide of potassium, are to be administered according to the indications afforded, for the purpose of allaying pain and soothing the nervous system. When suppuration is established, a full allowance of good nourishing food, with some alcoholic stimulant, should be given, and such tonics as seem most suitable. Small doses of opium at regular intervals often prove very beneficial. The complications that may arise, such as affections of the internal organs, &c., must be treated in accordance with general principles, but all depressing medicines as a rule should be avoided.

ARTHUR E. DUNHAM.

HEAT, Therapeutics of.—PRINCIPLES.—

The primary effect of external heat applied *locally* to the animal body is that of an excitant or stimulant. There occurs redness with throbbing of the small vessels, in the part to which the heat is applied, along with slight augmentation of temperature, and pain increased beyond a certain degree, heat ceases to be a stimulant, its prolonged action causing greater pain, exhaustion, depression, and, if the action be very intense, decomposition of the organized tissues. See preceding article.

Experiments have shown that by increased heat the electric currents in the nerves are destroyed. It may therefore be assumed that the nerves become less able to conduct impressions either to or from the brain, and that heat may act as a sedative to painful nerves.

Moderate heat applied generally, that is, to the whole body, produces a number of important physiological effects which are fully described in the preceding article, to which the reader is referred.

APPLICATIONS AND USES.—Heat is employed in the treatment of disease as a general or local stimulant, a local depressant, a caustic, or a counter-irritant, and that in the form either of *dry* or of *moist* heat.

Dry heat.—The primary exciting and stimulating action of heat may be made available to rouse the nervous and vascular systems. The use of the hot air bath (Turkish Bath), and that of the sand-bath are discussed in the article on BATHS. In some parts of the South of France, baths of hot sand (*arena calida*) are used in the treatment of rheumatism, paralysis, and spasm; the sand acting as a stimulant and anodyne. To restore the circulation, bottles of hot water are placed in the axillæ, and against the feet and thighs, in cases of collapse of the system, with coldness of the extremities and great failure of circulation, as in the treatment of collapse from the shock of an injury, or from such diseases as cholera, or of the apparently drowned.

Dry heat may also be applied to the abdomen, in the form of tins or bottles of hot water, or bags of heated salt or sand, to relieve painful spasm and colic. Hot water enclosed in an india-rubber bag is sometimes of service to allay undue irritability of the spinal nerves. The therapeutic application of heat as a counter-irritant will be found described elsewhere. See COUNTER-IRRITANTS.

Moist heat.—Heat and moisture together tend

to cause relaxation of the tissues, thus removing the tension and pain due to inflammation. Moist heat is employed locally in the form of the local vapour bath, fomentations, and poultices. *See FOMENTATIONS*; and *POULTICES*.

Moist heat is applied to the surface of the body generally, chiefly in the form of the vapour bath. *See BATHS*.

JOHN C. THOROWGOOD.

HEAT-STROKE.—A synonym for sunstroke. *See SUNSTROKE*.

HECTIC FEVER (*ſetids*, habitual).—*SYNON.*: *Fr. Hectique*, *Ger. Heetisch*.

ÆTIOLOGY.—The variety of fever thus named has long received special recognition, inasmuch as it presents certain prominent and peculiar features, as regards its course and attendant phenomena. It occurs in association with some wasting and exhausting disease, especially when this is accompanied by a profuse and constant drain from the system, and more particularly when there is chronic suppuration, with an abundant discharge of pus. Hectic fever is most frequently noticed in cases of pulmonary phthisis, in a large proportion of which it appears in various degrees during some part of their course, chiefly in the advanced stages. Other conditions deserving of mention in connection with which it may supervene are empyæma, especially if there is an external fistula, tubercular ulceration of the intestines, chronic purulent discharge from the kidney, hepatic abscess, chronic dysentery, and any form of external chronic abscess attended with much discharge. Fever of a hectic type sometimes occurs in cases of acute inflammation; and it is occasionally observed in chronic affections unattended with suppuration, such as cancer and lymphadenoma. Pathologically it seems to be connected with the absorption of pus or other morbid products into the blood. *See FEVER*.

SYMPTOMS.—Hectic fever is established gradually, becoming more and more distinct, until it assumes its typical characters. It is more or less paroxysmal, being at first indicated by slight pyrexia towards evening and during the night, the temperature being a little raised, and the pulse hurried. During the day there is no fever at this time, but as the case progresses it becomes constant, though exacerbations occur at night, and, it may be, also in the morning, the paroxysms thus occurring either once or twice within the twenty-four hours, and the pyrexia being remittent. In typical hectic there is a complete febrile cycle, beginning with chills or even a distinct rigor, followed by considerable heat of skin, the temperature continuing to rise, and ending in more or less profuse perspiration, especially about the head and chest, sometimes so abundant as to saturate the bed-clothes or even the bedding. Patients often feel subjectively very hot, the palms of the hands and soles of the feet having a burning sensation. The pulse tends to become very frequent and quick, and is easily hurried and excited, being at the same time weak, soft, and compressible. Not uncommonly a bright red or pink spot appears on each cheek during the paroxysm, known as the *hectic flush*, and this may contrast markedly with the general pallor of the face, the eyes being also bright,

clear, and sparkling. The mind is unaffected, and the mental faculties may be unusually bright and vivid. After a febrile exacerbation the urine may present excess of lithates. Hectic fever does not always show all its typical features, and even in the same case variations are noticed in the precise characters of the paroxysms. It is usually accompanied with other symptoms due to the disease with which it is associated; while it itself tends to cause wasting and debility, as well as a sense of exhaustion after each attack. In most instances a fatal termination ultimately ensues, but if the condition upon which hectic depends is curable, recovery may take place.

TREATMENT.—The first principle in the treatment of hectic fever is to attend to, and cure, if possible, the condition upon which it depends, and especially to diminish or stop suppuration. General tonic treatment will also help in preventing the paroxysms. These may be directly checked in appropriate cases by full doses of quinine, salicine, or other antipyretics, given before the usual time for their occurrence. Sponging the skin freely may also prove of service in some instances. The treatment of hectic in phthisis runs into that of night-sweats, and can be more conveniently discussed under that disease. *See PHTHISIS*.

FREDERICK T. ROBERTS.

HELIOSIS (*ἥλιος*, I expose to the sun).—A method of treatment for certain diseases, which consists in exposing the patient to the rays of the sun. The term is also employed as a synonym for sunstroke. *See SUNSTROKE*.

HELMINTHIASIS (*ἑλμύς*, a worm).—The condition of system upon which the development of worms in any part of the body depends. The term is also applied to the diseases characterised by the presence of worms.

HELMINTHICS (*ἑλμύς*, a worm).—Of or belonging to worms. A synonym for anthelmintics. *See ANTHELMINTICS*.

HELMINTHS (*ἑλμύς*, a worm).—This term is often employed in preference to one or other of the various synonyms with which it is regarded as equivalent (worms, intestinal worms, vermes, entozoa, internal parasites, and so forth). Thus, Von Siebold (who speaks of the *Helminthus* as forming a class of animals, nearly all of whose members are parasitic) admits that the only character common to the greater part of the whole group is their peculiar mode of life. The study of the helminths forms what is often called the science of *Helminthology*. In accordance with professional custom, it has been thought desirable, in the present work, to speak of the helminths as constituting the class *ENTOZOA*, under which heading, therefore, more detailed references are given. T. & C. COMBOLD.

HEMERALOPIA.—The etymology of this term is uncertain, and its real meaning has never been definitively settled. Some writers derive the word from *ἡμέρα*, the day, and *ὄψ*, the eye, and in conformity therewith, use it to signify *day-sight* or *night-blindness*, that is, a state of vision in which objects are seen by day-light or by strong artificial illumination, but become more or

less invisible when in deep shade or in twilight. Others, on the contrary, employ the term in the opposite sense of *day-blindness* or *night-sight*, deriving it from *hēmera*, *day*, and *priv.* or *ἀλῶς*, *blind*. It is used in the latter sense in this work, and may, therefore, be defined as a disorder of vision, in which objects cannot be seen well or without pain by daylight or by strong artificial light, but are more clearly or comfortably seen in a deep shade or by twilight. See VISION, Disorders of.

HEMIANÆSTHESIA (*ἡμισυ*, the half; *ἀν.* priv.; and *αἰσθησις*, I feel).—Paralysis of sensation affecting one side of the body. See PARALYSIS, Disorders of.

HEMIANALGESIA (*ἡμισυ*, the half, *ἀν.* without; and *ἄλγος*, pain).—Inability to painful impressions, affecting one side of the body. See SENSATION, Disorders of.

HEMICRANIA (*ἡμισυ*, the half, and *κράνιον*, the head).—Pain limited to one side of the head. The term is, however, generally used as synonymous with *migrain*. See MIGRAIN.

HEMIOPIA } (*ἡμισυ*, the half, and *ὄψ*,
HEMIOPSIA } the eye).—A derangement of vision in which only one half of an object is seen by one eye. See VISION, Disorders of.

HEMIPLEGIA (*ἡμισυ*, the half, and *πᾶρεσις*, I strike).—Paralysis of motion of one side of the body, sometimes applied to loss both of motion and of sensation. See PARALYSIS, MOTOR.

HEPATALGIA (*ἥπαρ*, the liver, and *ἄλγος*, pain).—Strictly this word signifies pain in connection with the liver. It has, however, been specially applied to a supposed neuralgic pain referred to this organ, coming on in paroxysms, and said to be of a severe character in some instances, so as to simulate hepatic colic. Whether there is any such affection is exceedingly doubtful, and probably in cases of supposed hepatalgia the neuralgia is either superficial, or there is some tangible but undiscovered cause for the pain, connected with the liver or some neighbouring structure.

FREDERICK T. ROBERTS.

HEPATIC DISEASES. See LIVER, Diseases of.

HEPATISATION (*ἥπαρ*, the liver).—A term applied to the condition produced by acute inflammation of the lung, in which the pulmonary substance becomes solid and friable, resembling somewhat the liver in its physical characters. See LUNGS, Inflammation of.

HEPATITIS (*ἥπαρ*, the liver).—Inflammation of the liver. See LIVER, Inflammation of.

HEPATOCELE (*ἥπαρ*, the liver, and *κύλη*, a tumour).—Hernia of the liver. See LIVER, Displacements of.

HEREDITARY (*heres*, an heir).—This term, as used in relation to medicine, is applied to the transmission of constitutional conditions, or of diseases, from parent to offspring. See DISEASE, Causes of; and PREDISPOSITION TO DISEASE.

HERMAPHRODITE (*Ἑρμῆς*, Mercury, and *Ἀφροδίτη*, Venus).—A term applied to an individual in whom the formation of the sexual organs is such as to give rise to the impression that both the male and the female organs are present. See MALFORMATIONS.

HERNIA (*hernia*, a rupture).—**DEFINITION.** This word is used in surgery to express the protrusion of any viscus from the cavity in which it is naturally placed. In this article, however, the observations are exclusively restricted to protrusions of the viscera of the abdomen through the walls of that cavity, and it is only intended to give a mere outline of the subject, its full discussion being beyond the scope of this work, as it is mainly connected with surgery.

GENERAL REMARKS.—Hernial displacements take place in both sexes and at all ages. The most striking objective sign of the existence of a hernia is a fulness or swelling in one or other of those regions of the abdomen where, from the anatomical construction of its walls, the tissues are weakest. When the parietes are defective, in consequence of local disease or injury, visceral protrusions may occur at those spots, and also, as the result of congenital malformation in both sexes, a fruitful cause of hernia being the non-closure of the vaginal process of the peritoneum at birth, or a patulous state of the umbilical aperture. Such a protruded viscus forms a hernial swelling or tumour. The tumour is composed of a sac, its contents, and the tissues outside the sac. The sac is composed of a prolongation of the peritoneum in most cases, and its orifice, neck, or abdominal aperture constitutes, with the tissues around it, a frequent cause of impediment to replacement or 'reduction' of the hernia. The hernia may be a part of any abdominal viscus, but those most mobile are usually displaced. Thus, in the majority of cases, either the omentum or small intestines, together or singly, form the hernia. The tissues outside the sac are those which exist in the region where the tumour is formed, and they are frequently described as the coverings of the sac.

Every hernial tumour possesses a neck, body, and fundus.

The first or earliest objective symptom of a hernial protrusion is an unusual fulness, as, for example, in the groin in a case of inguinal hernia. This swelling is transient, appearing and disappearing in relation to the actions or posture of the individual. When pressed with the finger the swelling disappears, but it is readily reproduced if the patient contracts the abdominal muscles, and then with the finger an impulse is felt, produced by the protruding viscera. By slow degrees the bulk of the swelling increases, until, if no support or 'truss' be used, very large tumours are formed.

CLASSIFICATION.—The most practical classification of hernial protrusions is based upon the usual triple division of the abdomen into regions, namely, the epigastrium, mesogastrium, and hypogastrium.

1. Protrusions in the epigastric region are very rare. They are (a) *Diaphragmatic*, and (b) *Epigastric*. The first is due either to relaxation of the

tear of the diaphragm muscle, or to its laceration. In some cases congenital deficiency of the muscle is the primary cause, in others the natural openings in the muscle become dilated. Signs of this hernia are very obscure, but when the protrusion depends upon laceration of the muscle, the occurrence of a recent injury may excite suspicion when associated with abnormal sounds in the thorax.

Phrenic hernia escapes at the region formed by the cartilages of the false ribs on either side of the linea alba. It is very rare and as the abdominal orifice of the sac is usually large, the hernia is easily reduced.

2. The hernia in the mesogastrium are (a) *Ventral*, (b) *Umbilical*, and (c) *Lumbar*. The term *ventral* is given to any hernial protrusion escaping through abnormal openings in the walls of the abdomen, to which no special name is given. They are seen in the region of the linea alba, above the umbilicus, but most frequently below; in the line of the linea semilunaris, and even opposite the muscular walls. Commonly of traumatic origin, their nature is clearly shown by the ready manner in which the protruded viscous can be pressed back into the abdomen. They sometimes ensue upon the weakening of the walls after distension, or upon the loss of tissue following abscess.

Umbilical hernia is met with at all ages and in both sexes. It forms a tumour at the site of the umbilicus in the first instance, and gradually descends over the linea alba as its bulk increases. Very soon after birth this variety of hernia appears. The protrusion takes place at the umbilical ring, and pushing before it the peritoneum, an acquired hernial sac is formed. To prevent, therefore, the development of the sac in infancy, and to assist the closure of the ring in the linea alba, a slightly convex disc of cork enclosed in washleather, should be strapped over the umbilical aperture. The prognosis of infantile umbilical hernia is favourable, for the aperture closes with age, and the tissues continue firm.

In adult life this kind of hernia is frequent in fat individuals. The tumour often acquires enormous proportions. Its contents consist of small intestine and omentum, with not uncommonly a portion of the transverse colon. Accumulations of faecal matter therein often give rise to obstruction, and the symptoms arising in consequence of this state more or less resemble those of strangulated small intestine. A correct diagnosis of their cause may usually, however, be arrived at from the history of the attack, the comparative mildness of the malady, and the alleviation of the symptoms by exerting the action of the bowels. The contents of this form of hernia, when of long standing, often become adherent or bound by bands to the sac, in which state they remain permanently irreducible.

When the protruded viscous can be entirely reduced within the abdominal cavity, a suitable, well-fitting truss should be worn constantly, and, if irreducible, one adapted to the circumstances of the case must be used.

Lumbar hernia takes place in the loins. It is a very rare variety, and usually occurs as the result of an injury.

3. The hernia in the hypogastrium are the most numerous and the most common. They include (a) *Inguino-scrotal* or *Inguino-labial*, above Poupart's ligament, (b) *Femoral*, below Poupart's ligament, (c) protrusions through the apertures of the pelvis in front, beneath the horizontal ramus of the pubes—*Oblurator*; (d) beneath the arch of the pubes—*Perineal*, (e) *Perineal*; (f) *Vaginal*, and (g) behind, through the ischiatic notch—*Ischiatic*.

Inguinal hernia is seen at all ages and in both sexes. The following varieties are described—the *oblique* or *external*; and the *direct* or *internal*. In the first, the orifice of the sac is outside the course of the internal epigastric artery, in the second it is internal to the same vessel. When the protrusion forming an inguinal hernia does not descend below the inguinal canal it is termed a *bubonocoele*, but when it occupies the scrotum or labium it forms an *inguino-scrotal* or *inguino-labial* tumour. The essential difference between the inguinal hernia of youth and of middle age is due to the constitution of the sac which encloses the protrusion. From infancy to early adult life protruding viscera escape from the abdomen into a serous sheath, continuous with the parietal peritoneum, the vaginal process of that membrane, which extends into the scrotum or labium. In middle life and afterwards the parietal peritoneum is thrust through the apertures or weak points in the abdominal walls by the protruding viscous. In this way two distinct kinds of hernial sac are formed, the first being due to a congenital defect, the second, to a mechanical and acquired cause. In practice, it is very important to bear these distinctions in mind. In the first kind a truss is applied to prevent the passage of the viscous into the sheath, in the hope that by this means its walls may unite and its orifice contract—in fact, to assist nature in accomplishing that condition the failure of which permits the protrusion to take place. But, in the second, a truss is used to prevent the protruding viscous pushing the peritoneum before it and so forming for itself a sac. Thus, if the development of the sac be arrested, there can be no hernial tumour.

Inguinal hernia occupy the inguinal canal, and are, therefore, in relation with the spermatic cord of the male and the round ligament of the female. They escape from the canal through the external abdominal ring into the scrotum or labium. The neck of the tumour is always therefore above Poupart's ligament, and to the inner side of the external pillar of the external abdominal ring. This anatomical fact constitutes the main distinction between inguinal and femoral hernia.

Femoral hernia forms a tumour at the inner and upper part of the thigh, immediately below the pubic attachments of Poupart's ligament. Those structures are in immediate relation with the neck of the sac. The protrusion escapes at the femoral aperture, the site of the entrance of the lymphatic vessels of the thigh to the abdominal cavity. The neck of the sac is therefore to the inner side of the sheath of the femoral vessels, although, in proportion to the bulk of the tumour, its body may overlie it, and even extend upwards above Poupart's ligament.

and outwards towards the crest of the ilium. The sac of a femoral hernia is always an acquired formation. Hence the importance of wearing a truss after observing the slightest indication of a femoral protrusion. For if the yielding, relaxed, parietal peritoneum be supported at the crural aperture by a well-adjusted pad, a visceral hernia must be avoided, as there will be no sac into which it can escape. In other words, arrest the development of the sac and there can be no hernia.

To discriminate between a femoral and an inguinal hernia, place the index finger upon the spinous process of the pubes, if the neck of the tumour is to its outer side, and the whole length of Poupart's ligament can be traced above it, a femoral hernia exists. Should precisely the converse conditions be ascertained, the tumour will depend upon an inguinal protrusion. Another method for diagnosis is the direct and careful examination of the site of the femoral aperture. If it is clearly and distinctly tangible and well-defined, it cannot be occupied by a hernial protrusion.

This hernia is most common in the adult female. It has been developed before ten years of age, is rare between that age and twenty, but very frequent in persons between twenty and forty years old. Prolific women are more frequently the subjects of this hernia than the single and sterile.

Oblurator hernia escapes from the pelvis through the thyrod foramen and traverses the canal normally occupied by the obturator nerve and vessels. It is rarely met with. A fulcra, rather than a tumour, is produced by the protrusion at the inner or pubic region of the thigh, beneath the pectineus muscle and accompanied by a peculiar numbness and pain, which may be traced to the distribution of the filaments of the obturator nerve. The lives of patients have been lost in consequence of overlooking these hernie, the cause of death being only ascertained *post mortem*.

Perineal, pudendal, vaginal, and ischiatic hernias are very rarely seen. The name assigned to each indicates the locality in which the tumour is formed, and for a special description of them, the reader must be referred to monographs on the subject of this article.

EFFECTS AND TREATMENT.—We must next, as briefly as possible, describe generally the various morbid conditions which the hernia itself may undergo, and the means by which fatal consequences from such conditions may be averted.

All hernial protrusions are reducible or irreducible; that is, they can be restored to their normal situation, or they may be permanently confined to the region in which they are produced.

The treatment of all reducible hernie consists in the employment of means to prevent the escape of the protrusion. To effect this object various kinds of bandages or trusses have been devised. Each kind of hernia requires its special form of truss, and every individual should, as far as practicable, obtain a truss well fitted to his or her configuration. The essentials of a good truss consist in the spring having sufficient power to support the hernia and prevent its escape, while it should not be so strong as to

injure the structures about the abdominal rings. The pad should be firm, of a shape suitable to the case, and of a size not inconvenient to the wearer.

The irreducibility of a hernia depends on its bulk, adhesions, and special anatomical conditions. Under such circumstances special bandages must be employed.

But other much more important morbid causes of the protruded viscera than the above, cause impediments to the reduction of a hernia, namely—1. constriction by the tissues around the orifice of the sac; 2. accumulation of fecal matter in the protruded viscera, 3. inflammation of the hernia; and 4, strangulation when a part of the alimentary canal forms the hernia.

1 Those hernie—for example, the inguinal—which pass through openings in the muscular walls of the abdomen, are liable to constriction from contraction of the muscular tissue. Inguinal hernie of long standing, and more than ordinary bulk, are very prone to become irreducible in consequence of muscular contraction. Such cases are well adapted to illustrate the effects of anaesthetics, and their influence on muscular irritability. If the patient be placed under the full influence of chloroform, the abdominal muscles become relaxed, and the hernia quickly reduced.

2. Those hernial protrusions formed of large intestine, such as occur at the umbilicus, frequently become irreducible from accumulations of stercoraceous substances. In these cases enemata, and even purgative medicines, frequently relieve the symptoms.

3. Inflammation excited in an omental protrusion may cause temporary and even permanent irreducibility. Local and constitutional symptoms of a rather severe type sometimes attend such cases. The usual methods adopted to induce resolution must be employed.

4. A morbid state of the protruded bowel termed *strangulation* has next to be described. A patient the subject of this state remains in the greatest danger to life so long as the exciting cause, the constriction of the bowel, exists. Hour by hour that danger increases, and although rare instances of recovery might be quoted after the continuance of strangulation for many hours, the majority of patients die because the intestine was not liberated early enough. A hernia is described as *strangulated* when subject to a constriction which at first impedes, and sooner or later arrests the circulation of the blood in its capillary vessels. The passage of stercoraceous material is necessarily stopped. The local and constitutional symptoms are strikingly characteristic. Very frequently the first symptom is vomiting, unaccompanied by any alvine evacuation. The vomiting continues, and is excited by ingesta. This state is probably due to mere obstruction of the alimentary canal, but it ought always to excite the anxious solicitude of the medical attendant, to ascertain whether the patient has any outward signs of a hernial tumour. He must examine those regions at which protrusions commonly occur, and never rest content with the statements of the sufferer. At first the pulse is not affected in a very marked way, but as vomiting continues the heart beats more

rapidly, whilst the pulse becomes weaker and contracted. The surface, especially that of the extremities, becomes cold, the countenance aged and anxious, the visage, lips, and hands shrivelled and bluish, the prostration extreme. The tumour is painful when touched, and it may have increased in size and become tense. All these facts indicate progressive morbid changes in the tissues of the strangulated bowel, as well as in that part of the alimentary canal above the hernia. Besides the mere act of vomiting all ingesta, the characters of the fluid vomited must be carefully noted. Usually, at first, it is the food last swallowed, more or less digested and mingled with bile, in the second stage it becomes yellowish and greenish, and at last it is steatoraceous, that is, offensive to smell, of a brownish colour and frothy, and often in great quantity. Now the only treatment of these urgent symptoms consists in the liberation of the bowel by surgical means. In the mean time palliatives may be employed, opium administered by the mouth, emulsiata injected, local applications of ice used, and gentle taxis applied.

HERNIA CEREBRI. See BRAIN, Malformations of, and SKULL, Diseases of

HERPES (*ἑρπης*, I creep). **SYNON :** Fr *Herpès*, Ger *Flechte*.

DEFINITION -- A term applied to an eruption of vesicles on an inflamed patch of integument.

ÆTIOLOGY -- A predisposing cause of herpes is the gouty or rheumatic diathesis. It is often excited by chill or by irritation of a mucous membrane--of the air-passages in the case of herpes labialis, and of the urinary passages in herpes præputialis.

VARIETIES AND SYMPTOMS -- The commonest forms of this disease are *herpes zoster*, *herpes labialis*, and *herpes præputialis*, to which may be added *herpes facialis*, *herpes collaris*, *herpes cruralis*, and so forth. In herpes labialis and præputialis, the inflamed patch is generally single, but in the other forms the patches may range from five to ten in number, and vary in size from a small blotch, scarcely an inch in diameter, to one of three or four inches. The patches follow the course of distribution of the nerves, and on the trunk of the body form a kind of festoon, extending from the spine behind to the middle line in front. This is especially the case in herpes zoster, likewise called *zona* and *shingles*, where the blotches, following the course of one or more intercostal nerves, form a half belt or circle around the waist. The eruption of herpes is unilateral. It has a regular course of from ten to twenty days.

The vesicles of herpes are developed in groups, ranging in number from two or three to twenty or thirty, and in size from that of the head of a pin to that of a small pea. The fluid contained within them is at first transparent, it then becomes opalescent opaque, purulent, and sometimes purplish from admixture with blood, and finally the eruption terminates in a scab more or less dark-coloured, and more or less deeply imbedded in the skin, which often leaves at its fall a permanent cicatrix.

Herpes is accompanied with a burning ting-

ling, and pricking sensation, and occasionally with severe neuralgic pains. The neuralgia may either precede or follow the eruption; and occasionally it is intense and of long duration. See Dr Sangster, *Lancet*, vol. i 1882.

TREATMENT. -- The treatment of herpes is both constitutional and local. In slight cases, as the eruption runs a regular course, and tends to spontaneous cure, no constitutional treatment is necessary. If thought desirable, treatment should be restricted to regulating the digestive and assimilative functions, strengthening nerve-power; and, where severe pain or neuralgia is present, administering quinine or sedatives. *Locally*, dressing with flour or some absorbent powder affords relief, and especially the application of a lotion of oxide of zinc and lime-water. Over these should be placed a sheet of cotton-wool; and the latter must be kept in place by means of a light bandage. In very painful cases, the subcutaneous injection of morphia may be required, or the application of anodyne liniments.

ERASMUS WILSON.

HETEROLOGOUS (*ἑτερος*, other, and *λόγος* nature). A word used to characterize any morbid product, whether fluid or solid, which is different in composition or structure from the normal fluids or solids of the body.

HETEROMORPHOUS (*ἑτερος*, other, and *μορφή* form). Applied to new formations which are different in form and structure from the normal tissues.

HETEROTOPOUS (*ἑτερος*, other, and *τόπος*, a place). Misplaced. A term applied to the appearance either of a normal tissue in an unnatural situation -- for example, of hairs on mucous surfaces, or of morbid growths in an usual place -- for instance, of epithelioma in nervous tissue.

HICCUP OR HICCOUGH -- **SYNON :** *Singultus*, Fr *Hoquet*, Ger *der Schlucken*.

DESCRIPTION. Hiccup, according to physiologists, is a sudden spasmodic descent of the diaphragm accompanied by a spasmodic closure of the glottis, the characteristic noise being caused by the incoming column of air striking against the partially closed glottis. The assumption of a spasmodic closure of the glottis in hiccup seems scarcely warrantable. Normally the descent of the diaphragm in each respiratory act is accompanied by a contraction of the posterior crico arytenoid muscles, which causes an outward rotation of the arytenoid cartilages, and a dilatation of the glottic aperture. The diaphragmatic and the laryngeal acts keep time together, and in health the rhythm of sixteen or eighteen to the minute is maintained. It, however, the diaphragm give a sudden descending jerk irrespective of any respiratory need, as is the case in hiccup, and this jerk occur at a time when the dilators of the glottis are not acting, a noise will be produced by the rush of air through the insufficiently widened glottic aperture. It seems certainly possible to account for the noise of hiccup by the mere fact of the descent of the diaphragm occurring when the glottis is not properly open. The noise is not a constant phenomenon, and during an attack of

hiccup it never occurs during ordinary inspiration, or without the spasmodic action of the diaphragm, although the latter phenomenon may occur without the former.

ÆTIOLOGY.—Hiccup may be produced by any irritation of the phrenic nerve—its origin, its course, or the ultimate twigs which are distributed to the under surface of the diaphragm. Undue distension of the stomach by being overfilled with food or drink, or by an accumulation of wind due to faulty digestion, is the most common cause of hiccup. Its occurrence from this cause is far more common in children than in adults. Convulsions and muscular spasms generally are more easily caused in the young, and hiccup in this respect follows the ordinary rule. Hiccup is produced by direct, or by reflex irritation. With many persons the introduction of hot spiced or peppery foods into the stomach immediately produces hiccup, and the writer knows one or two persons in whom hiccup is produced by the passage of hot fluids through the pharynx. It is a frequent symptom in peritonitis when the peritoneal covering of the diaphragm becomes affected. It sometimes occurs in cases of cancer of the stomach, occasionally perhaps from overdistension of the organ, but more often from an extension of the cancerous disease to the peritoneal surface of the stomach. It is occasionally a troublesome symptom during convalescence in cholera, and is often accompanied by eructations of wind, and sometimes by vomiting. If hiccup occur with any persistence in the course of typhoid fever, it is often an indication of perforation and the onset of general peritonitis. Although most frequently a symptom of gastric or abdominal disturbance, hiccup occasionally occurs as a true neurosis. It may accompany hydrocephalus or meningitis, and is then due probably to an implication of the cerebral origin of the phrenic nerve. Cases of obstinate hiccupping in hysterical subjects have been recorded, and cases of paroxysmal hiccup have been observed by Living, Prichard, and others, which have been regarded as instances of modified epilepsy.

TREATMENT.—The treatment of hiccup will depend upon the cause. An emetic to empty the stomach, or a stimulant to increase its natural peristaltic action, will often give relief. If we can succeed in producing a forcible action of the diaphragm, we may often succeed in curing it, as it were, of the trick of spasmodic action. Attempts to count a hundred without drawing breath, or to hold the breath for a minute, are familiar remedies for hiccup, and, by producing a feeling of suffocation, and necessitating a violent descent of the diaphragm, they are often successful. Warm applications or counter-irritation applied to the diaphragmatic region or over the cervical spine, may occasionally give relief. Pressure upon the trunk of the phrenic nerve by means of the finger applied over the *scalenus anticus* muscle, is said also to have given relief occasionally in obstinate cases. Amongst the drugs which have been recommended for the relief of hiccup are chloroform (administered internally), either alone or combined with opium, camphor in the form of a spirit solution, in doses of *twelve drops* and upwards, valerianate of zinc,

belladonna, bromide of potassium, musk, antacids, and in very severe cases morphia administered hypodermically. G. V. POORE.

HIPPURIA (*ἵππος*, a horse, and *οὐρ*, urine).—The condition of the urine in which it contains hippuric acid in excess. *See URINE*, Morbid Conditions of.

HISTRIONIC SPASM *chastro*, an actor). A synonym for facial spasm, so called on account of the contortions of the face to which this affliction gives rise. *See FACIAL SPASM*.

HIVES.—A popular term for chicken-pox. *See CHICKEN-POX*.

HOARSENESS (*Six*, *has*, having a rough voice).—Roughness of the voice, due to disease or disorder connected with the larynx. *See VOICE*, Disorders of.

HOBNAIL LIVER.—A name given to a cirrhotic liver, when it presents small prominences on its surface, resembling hobnails. *See LIVER*, Cirrhosis of.

HODGKIN'S DISEASE.—A synonym for Lymphadenoma. *See LYMPHADENOMA*.

HOMBURG, in Germany. Common salt waters. *See MINERAL WATERS*.

HOMICIDAL INSANITY. *See CRIMINAL IRRESPONSIBILITY*, and *INSANITY*, Impulsive.

HOMOLOGOUS (*ὁμός*, like, and *λόγος*, nature).—In pathology this term is applied to new growths presenting the same structure as normal tissues, such as fatty or fibrous tumours.

HOOPING-COUGH. *See WHOOPING COUGH*.

HORDEOLUM (*hordeum*, a barley-corn). A synonym for sty. *See STYE*.

HORN-POX.—A popular term for a variety of chicken-pox. *See CHICKEN-POX*.

HORNS.—*Saxon: Cornua*. **DEFINITION.**—Horns are epidermic and epithelial formations, consequent on hypertrophy of the horny product of the integument.

DESCRIPTION.—Horns generally occur singly. Sometimes they attain a size of several inches in length and in circumference. They have been met with on all parts of the body, more particularly on the scalp, the face, the glans penis, and the glans clitoridis.

PATHOLOGY.—When the inspissated product of the follicles of the skin, consisting of laminated epithelium and sebaceous matter, is exposed to the air, it dries, becomes hard and transparent, and is in fact converted into a mass having most of the properties of horn. This is the principal source of the horns of the integument—an accumulation of the contents of a follicle; the protrusion of that substance through the dilated aperture of the follicle, sometimes through a large opening resulting from atrophy or ulceration, its desiccation by the atmosphere; and its growth by continued additions to its base. Being essentially the protrusion of a soft substance through a constricted aperture, the surface of the

horn will be modelled in figure by the shape of that aperture; in consequence of desiccation, its shaft will be smaller than its base, and it will be liable to be bent or twisted in the operation of protrusion. Hence these horns are generally curved or twisted, and have been compared to the beak of a bird, or the horn of the goat. A section of the horn affords similar evidence of its manner of formation and growth, it being always laminated in structure.

Another kind of horn is sometimes met with on the glans penis and clitoridis, and is the product of hypertrophy of the papillæ. This form of growth is fibrous in structure, like a wart, which in fact it closely resembles, whilst in the same situation conereted masses are occasionally formed, constituted by a combination of both processes, namely, papillary hypertrophy and accumulation of follicular substance. There is, however, an important difference between the two kinds of horn, the sebaceous and the epidermic, namely, that the former is the mere result of increased activity of function, whilst the latter is the consequence of hyperæmia or inflammation.

TREATMENT.—Horny matter being susceptible of disintegration by moisture, the sebaceous horn may be so thoroughly softened by envelopment in a waterproof covering, or by a poultice, as to be easily broken away at its base. The follicular bed from which it has been removed may then be cleared by a small scoop, when the sac will contract and close. Sometimes it may be thought desirable to sponge the surface with a solution of chloride of zinc or sulphate of copper, but operation by the knife seems quite uncalled for. In the instances of epidermic and epithelial horn, however, it will be necessary to have recourse to caustics, especially potassa fusa, and when the case evinces great obstinacy or where an epitheliomatous degeneration is suspected, the use of the knife becomes essential.

ERASMUS WILSON.

HORRIPILATION (*horreo*, I bristle up, and *pilus*, a hair)—A sensation of chilliness and creeping, the hairs appearing to stand on end.

HOSPITALS.—The subjects having relation to hospitals will be treated of under the following heads—I HOSPITALISM, II HOSPITALS, Administration of, III HOSPITALS, Construction of, IV NURSING, and V NURSES, Training of. The reader is referred to these several articles.

HOSPITALISM.—The term 'Hospitalism' was introduced into medical literature by Sir J Simpson (*Edinburgh Medical Journal*, March, 1869), but, as far as the writer can see, no exact definition of it was given by its author. It, however, was evidently intended to signify 'the hygienic evils which the system of huge and colossal hospital edifices has hitherto been made to involve'—to use Sir J. Simpson's own words. These evils appeared to him so evident, and so necessarily connected with the size of the hospital, that he taught (and in fact the sole object of his papers was to teach) that our system ought to be revolutionised—'hospitals changed from being crowded palaces, with a layer of sick on each flat, into villages or cottages, with one, or at most two patients in each room; the village constructed of

iron instead of brick or stone, and taken down and rebuilt every few years.'

Mr. Erichsen has, to some extent, accepted the teaching of Sir J. Simpson, though he allows that some of it is very questionable. His tract on the subject of Hospitalism has the advantage of being written in a more sober style than Sir J. Simpson's, and also of putting the question in a clearer light.

By the term, he says, 'is meant a general morbid condition of the building, or of its atmosphere, productive of disease . . . Doubtless' says Mr. Erichsen, 'all the septic diseases that are met with in hospitals may be encountered in the practice of surgeons out of these institutions, but they are unquestionably infinitely more common in hospital than in private practice, and their causes are certainly different.' The writer believes, on the contrary, that if a hospital be properly managed there is no general morbid condition of the building—that there is no reason for thinking that septic diseases are more common relatively in hospitals than out of them, and that their causes are identical wherever they occur.

And if the term Hospitalism is to be taken in the sense in which Sir J. Simpson evidently intended, that is, as meaning to convey the idea that there is an inevitable tendency to the generation of septic disease in large hospitals, that that tendency becomes greater as the size of the hospital is increased, and that it increases as the hospital grows older, the writer has no hesitation in saying that there is no such thing as Hospitalism. No doubt the aggregation of the sick and wounded in hospitals is a cause of danger, and much care and vigilance is required to keep hospitals healthy. But the dangers are in no sense peculiar to hospitals. The surgical affections which spring up in hospitals—erysipelas, phagedæna, pyæmia, and allied affections—all of them prevail in private practice, and, as far as has been shown, prevail equally. Further, although the perfect publicity of our hospital practice enables us to obtain tolerably accurate data for a comparison of the experience of the smaller and larger hospitals of this and other towns, no one has ever seen the least reason for believing that the smaller are in any respect healthier than the larger, while several of the hospitals that have been longest built are renowned for their healthy condition, and in many large hospitals, parts of which are ancient and other parts modern, the former, if equally or better constructed, are (under similar conditions of cases and management) as healthy or more healthy than the parts more recently built.

The subject is not one which can be passed over as dealing with an insignificant question or one of a trivial interest only. The doctrines which Sir James Simpson taught led him to deprecate

¹ On Hospitalism p. 37.

² It is not, of course, meant that pyæmia, for instance, is seen as often in private as in hospital practice, because the causes are less often met with in the former than the latter; but, if due allowance be made for this obvious consideration there is much reason to acquiesce in the conclusion to which Sir J. Paget's ample experience has led him, that pyæmia is just as frequent in private as in hospital practice (*Clin. Soc. Trans.* vol. vii. p. lvi.). Erysipelas seems to be more frequent and more fatal at the present time in London private practice than in hospitals.

altogether the construction of any hospital of considerable size, and to advocate some extravagant scheme for substituting small detached temporary sheds for our present permanent hospitals. The same views led Mr. Erichsen to say that when a hospital had become, as he phrased it, 'pyæmia-stricken, it ought to be destroyed,' while similar ideas have led others, such as Dr. Farr and Miss Nightingale, to question whether hospitals had not destroyed more lives than they had saved. Such doctrines should not be passed over in silence, since they exercise a great influence on the public, on whose co-operation the efficiency of our hospital system is to a great extent based. And certainly a theory which has received the support, however qualified, of so eminent a hospital surgeon as Mr. Erichsen, cannot be considered as of no importance.

It is therefore necessary to point out to the reader that the theory, as so stated (and stated quite correctly after Sir J. Simpson's writings), is utterly disproved by the experience of all well-managed hospitals, both before and after the introduction of the antiseptic method of dressing wounds. It must be noticed in the first place, that the basis of the theory was entirely what is called 'statistical,' that is, a hasty inference from figures, showing the results of a large number of cases on either side. Now nothing is more dangerous than to draw conclusions from such figures, which are quite unsupported by any histories of the cases on which they are founded. The success of a surgical operation depends more on the antecedents of the operation than on its consequents and the healthiness of hospitals depends far more on other circumstances than on their construction, size, or age. Nay more, the success of surgical operations does not necessarily vary with the healthiness of the hospital. In the healthiest hospital a careless surgeon, house-surgeon, or nurse may make havoc of the major operations while all is going on well with the general run of patients.

For all these reasons, any one of which would be sufficient, the conclusions of Sir J. Simpson are to be utterly repudiated, and to be considered the more mischievous because, while they allege imaginary causes of danger, they thereby conceal those which are real and certain, and necessarily induce surgeons and managers of hospitals to overlook details, attention to which is always followed by success in the treatment of grave surgical cases, and by a condition of hospital hardly if at all inferior to the best circumstances under which private practice is carried on.

The writer must not be misunderstood, as if he thought the details of hospital-construction unimportant. The principles of construction which are now accepted for the building of a hospital will be found at pp. 647-652, but it has been shown to demonstration that, provided wards be well, but not excessively, ventilated, and kept perfectly clean, and provided the beds are far enough apart, the precise ground plan of the hospital matters little—that the

doctrines so much insisted on by the French writers on hospitals as to the superiority of the 'pavilion plan,' as to the unhealthiness of upper stories and so on, and which have been adopted as if they were unquestionable truths by many writers on the subject, have led to much waste of money on buildings too scattered for hospital service, which have turned out to be no healthier than the more compact and convenient structures which they superseded. But we ought not, in reaction from these exaggerations, to undervalue the importance of good ventilation, good aeration, proper isolation of beds and, above all, scrupulous cleanliness, in hospital wards. These essentials being secured, the writer is persuaded that a hospital may be just as healthy with thirty wards as with three, with twenty patients in each ward as with two, and with five stories as with one. Far more important, and far too little thought of, till within the last few years, is the amount of attention given to the personal care of the patients. This is particularly the case in the treatment of open wounds. Everyone who has been much in hospitals must have often seen, and especially abroad, surgeons, dressers, and nurses hurry from one patient to another, hardly washing or wiping their instruments, still less their hands, and using the same dressing materials for one case after another. Surgical practice cannot be safely carried on in this way, however healthy in itself the hospital may be. The first care of a surgeon in charge of hospital-wards ought to be to impress upon all his assistants, and never to forget in his own person that the success of surgical practice depends more upon minute care in the dressing of cases, than on all other matters put together. Our surgical wards have become far more healthy since the introduction of antiseptic surgery,¹ and that this must be largely due to the increased care in the minutiae of surgical treatment which has followed on the discussion of this method is proved by the fact that it is as conspicuous in some of those who reject as those who follow Mr. Lister's teaching.

If it were not true that the septic diseases, or erysipelatos diseases, which interfere so much with the success of operations in our hospitals, depend in a very large proportion of cases on the method of dressing the wound and not on matters conveyed by the atmosphere, how could the success of the so-called 'open method' of dressing wounds be explained? In this method the wound is left freely exposed to that hospital air which is we are told, charged with deadly miasmata. The size of the wards, number of beds, &c. are all of course unchanged, but care is taken to see that the wound is well drained of all putrefiable discharges and kept perfectly clean. If Sir J. Simpson's theory were true, we ought to have an increased mortality following on the freer exposure to this deadly atmosphere. On the contrary, the perfect drainage of the wound, and the care taken to keep it free from all putrefying matters, are followed by results

¹ On Hospitalism, p. 28.

² The writer lays less stress on the total absence of any guarantee for the accuracy of Sir J. Simpson's table of cases in private practice, and is willing for the sake of argument, to assume that the figures are correct.

³ The late Mr. Callender stated it as his deliberate opinion that the great surgical operations are ten times more successful in hospitals now than they used to be in the past generation.

which can hardly be surpassed. Thus Dr. James Wood, of the Bellevue Hospital, New York, relates, that in wards which had been recently vacated on account of an outbreak of puerperal fever, he treated fourteen successive cases of unselected amputation of the limbs successfully, by merely leaving the flaps unmoisted, the raw surfaces exposed to the air, but carefully drained and all putrescible matters continually removed,¹ and this is only one of many proofs which have recently been given of the fact that there are many other plans of treating wounds besides that which is specially designated 'antiseptic,' under which, conjoined with proper construction and general management, a hospital may be as healthy as a private house.

This statement, which is made after long experience, and with a conscientious conviction of its truth, by no means asserts that it is as easy to keep a hospital healthy as a private sick-room, or, in other words, that the aggregation of the sick and wounded involves no dangers. Such a doctrine would be absurd, but the dangers are the same in kind, and the precautions required are the same, with a single exception. Hospitals, like private houses, must be kept well-aired, well-drained, scrupulously clean properly, but not excessively, lighted,² and so forth. The great difference in the precautions required to ensure the salubrity of hospitals and private houses is, in one word, to guard against direct infection and this may occur in two ways. Surprisingly, infection is carried directly by careless dressing—and every hospital surgeon must have remarked it—as he himself is more watchful and careful, and as he has the good fortune to be surrounded by more careful assistants, his cases do better, and in the present healthy condition of most of our large London Hospitals, such precautions of themselves suffice to raise the success of surgical practice to the same level as it reaches in private houses. The second way in which infection may be carried is by direct proximity or contact. This is more important in medical cases, and the obvious danger of the spread of infectious fevers has led the managers of most of our general hospitals to exclude such diseases from their wards as small-pox, scarlet fever, and typhus, while other affections are admitted, which, though contagious, are so in a less degree, as typhoid fever, erysipelas, diphtheria, &c. Enough or more than enough, has been done in this direction—that is, the public safety might be as well consulted if typhus and scarlet fever cases were still admitted (as before the institution of special hospitals for such cases they used to be) into the wards of our general hospitals in small numbers, and under strict precautions. Anyhow, it appears that there is little if any evidence of spread of disease from such cases reputed to be infectious as are still to be found in our general hospitals. Hearing that some distinguished surgeons teach confidently that pyæmia and erysipelas are usually propagated by contagion the writer has often watched the progress of such cases when originating in

hospital or admitted from without, but has never been able to verify any spread of the disease from them, though he does not deny the possibility of such an occurrence.

To sum up the whole matter—the writer would define the term 'Hospitalism' as expressing the danger which exists in hospitals of contamination from the aggregation of patients—and would add that the extent to which such contamination prevails has been greatly exaggerated by theoretical writers, that, as far as the general atmosphere of the ward is concerned, the danger may be, and appears in all well-managed hospitals really to be, obviated by ventilation and cleanliness—and the more immediate danger from the contiguity of patients cannot be shown to produce any appreciable effect, while the danger of contamination of wounds by putrefying materials demands constant vigilance to counteract it, but with such vigilance seems to be so far counteracted that hospital practice is, for anything we know, as successful as private practice in similar cases. This is not an entirely satisfactory result, inasmuch as practice in a hospital, where every patient is under the strictest regimen and surveillance, ought to be much more successful than private practice, where the conditions are very different in these respects, but we are making rapid advances towards this desirable and perfectly attainable end.

T. HOLMES.

HOSPITALS, Administration of.—The administration of a hospital should be so framed as to enforce the necessary economy consistent with the due supply of the requirements for the sick.

Governing Body.—The administration is in the hands of a governing body, which usually consists of a committee or board, with an officer in direct communication with them, who acts as their representative. The governing body provides for the general supervision and discipline of the establishment, and for the financial arrangements. In this body is vested the appointment and removal of all members of the staff of the hospital. It makes all general regulations after consultation with the professional department, as to internal economy, admission and discharge of patients, distribution of beds, dietary and other matters. It takes steps for raising the funds to support the hospital, and regulates the expenditure.

Governor or Treasurer.—The active representative of the governing body is generally termed Governor or Treasurer. He exercises a general supervision over the structure and the discipline of the establishment. The chief executive officer immediately under the governing body is called the *Steward*, or sometimes the *Secretary*. He has the control of all servants not included in the nursing staff—such as porters, ambulance-men, engine-man, bath-assistants, and other male attendants. He sees that all structural appliances are in good order, and that cleanliness and discipline are maintained throughout the building. He controls the issue of all orders for the supply of goods, provisions, fuel, &c., and watches that they are used with a due regard to economy. He countersigns all orders for payment after they are passed by the treasurer,

¹ *New York Medical Journal*, Jan 1876.

² Most of our hospitals are too light, and too destitute of the means of excluding the light. No doubt a flood of light in the ward is very useful in detecting dirt, but it actively interferes with the repose which many sick men and women require.

and is responsible for the hospital accounts. He sees that the records of admission, discharge, and death are duly kept by the professional staff. He is responsible for the safe custody of clothing, money, and property brought in by the patients, till their discharge. He has charge of the correspondence.

Clerk, or Assistant Steward.—The secretary or steward is assisted by an assistant or clerk. This latter receives all provisions and stores, sees that they are correctly delivered, and is responsible for their safe custody until distributed to an authorized person. He sees that the diet-tables are prepared from the prescription papers, and that the articles of food supplied to patients are strictly in accordance with the diet-table, or else specially ordered by the physician or surgeon.

Professional Staff.—The professional staff directs the proceedings to be taken for the well-being and cure of the patients. It consists of the consulting and visiting physicians and surgeons, the assistant physicians and surgeons, and the resident and house-physicians and surgeons, and assistants continually present in the hospital.

Medical Committee.—The professional staff forms a medical committee with a specified quorum. This committee is consultative only, and advises the governing body on all matters concerning the medical and surgical departments of the hospital, the admission and discharge of patients, the distribution of beds, the dispensary, the in-patients, out-patients' department, and the students. The medical committee, moreover, puts forward recommendations for the purchase of instruments, apparatus, and medicines. The committee provides for a descriptive record of cases admitted into the hospital, and for the efficient instruction of students.

Physicians and Surgeons.—The physicians, surgeons, assistant physicians and assistant surgeons undertake the charge of the wards and out-patients' departments, and attend at the hospital at fixed times. The physicians and surgeons order the diet of the patients, and no article of diet which does not appear in the diet-table is supplied unless specially ordered by them.

Resident Medical Officers.—The resident medical officers control the treatment of patients in the absence of the physicians and surgeons, and have a disciplinary control over the dressers and clinical clerks. They decide on the admissibility or otherwise of applicants for relief, when not admitted directly by the physicians and surgeons, as well as on the wards in which the in-patients are to be placed, and are responsible for their care until seen by the physicians and surgeons. They visit the wards and dispensary, according to the regulations, to see that the patients are duly attended to. They superintend the conduct of the assistants of the medical officers, and of the dispenser and his assistants, of pupils (if any), and of patients, give notice of any misconduct of the nurses and servants to the matron or lady superintendent; and inform the governor or secretary, the physician, surgeon, and governing body, of any matter requiring their attention. They are responsible that the records of cases are

properly made out. In most cases, however, this duty is now performed by *registrar*.

Dispenser.—The dispenser acts under the resident medical officer subject to regulations laid down by the governing body.

Nursing Department.—The nursing department is under a trained matron, who should be lady superintendent of the training school, and head of all the women employed in the hospital.

Matron or Lady Superintendent.—The whole responsibility for nursing, internal management, care of linen and housekeeping, and the discipline and training of nurses is vested in the trained female head of the nursing staff, by whatever title she be called. To the governing body of the hospital she is responsible for the conduct, discipline, and duties of her nurses. To the governing body and the physicians and surgeons in charge of wards she is responsible for the care and cleanliness of the wards for the care and cleanliness of the sick, and for the linen. She is responsible to the medical officers that their orders about the treatment of the sick are strictly carried out. To fulfil these responsibilities, she has the power of engaging, appointing, and dismissing all nurses, female servants, and probationers, subject of course, to the general control of the governing body. The nursing establishment cannot be made responsible on the side of discipline to the medical officers, or the governor of a hospital. Simplicity of rules, placing the nurses in all matters regarding management of sick absolutely under the orders of the medical staff, and in all disciplinary matters absolutely under the lady superintendent or matron, to whom the medical officers should refer all cases of neglect is very important. Any remissness or neglect of duty is as much a breach of discipline as drunkenness or other bad conduct, and can only be dealt with to any good purpose by report to the matron. But neither the medical officer nor any other male head should ever have power to punish for disobedience. His duty should end with reporting the case to the female head, who is responsible to the governing authority of the hospital as all her nurses and servants are, in the performance of their duties, immediately responsible to the matron only. If the matron or lady superintendent does not exercise the authority entrusted to her with judgment and discretion, it is then the legitimate province of the governing body to interfere and to remove her.

The matron resides in the hospital where her nurses and probationers are at work.

In a hospital of, say, above 300 beds, and with a training school of, say, above twenty probationers (which all such hospitals ought to include), the trained matron should have three trained representatives or assistants—one in the training school as mistress of probationers or home-sister, and two in the hospital—one by day as assistant matron (or superintendent), and one by night as night superintendent of nurses, and of these two the night representative is the more important. Besides the trained assistant matron (superintendent) who should have such inspection of the wards as the matron may commit to her, the matron will

require one linen-assistant and housekeeper, who might also have the charge and inspection of the nurses' rooms, if the trained assistant matron has not time. She should 'mother' the ward-maids, and have some 'gathering' for them.

Nurses and Servants.—Under the matron there should be distinct grades of nurses, and distinct duties for each grade:—1 Trained chief nurses (ward sisters.) 2 Trained nurses (day.) 3 Trained nurses (night), at least equal in pay and status to the day-nurses. 4 Probationers in training. 5. Ward-maids, and nursemaids for children's wards. 6 Dormitory and stairs women. 7. Female cook, and her assistants under the house-keeper. The hospital cook in a large hospital would probably be a man, and under the steward. The sisters nurses, and probationers would require a female cook, under the matron. All women employed in the hospital should reside in the hospital.

Night Superintendent.—The (trained) night superintendent of nurses should be in charge of the night-nursing, in communication with the ward sisters, as well as of the night-nurses, should see that the ventilation and temperature of the wards is maintained—directed by the medical staff. She must be one qualified not only to have charge of nurses and have some 'gathering' for night-nurses by day, but to train probationers told off to accompany her at night, to their own benefit and hers.

Assistant Matron.—The assistant matron is to have special charge over the nurses' rooms, to see that the nurses rise in time to wash themselves, strip their beds, empty their slops, and have breakfast, before going on duty, that later they make their beds and put their rooms in order, that they never wash their own clothes in their own rooms, but all nurses' washing should be done for them, that they go quietly to bed at night, and lights be put out at a certain hour, that their rooms are always clean, in order, wholesome and cheerful. Without this constant supervision what is necessary for the nurses' health is not done, the same for night nurses is yet more important. Nurses' meals should always be presided over by some such authority.

The hospital night nurses should have two hot meals in the common dining room, it might be in the probationers' home, say at 9.30 a.m. and 9.30 p.m., ready and prepared for them. And sisters, staff nurses, and ward-maids should have, though at different hours—as all cannot be absent from the wards at once—dinner and supper, each set together in a common dining-room, away from the ward air. No nurse should have to prepare her meals for herself.

Laundry.—In small and moderate-sized hospitals, when there is a laundry attached to the hospital, the supervision should be under the lady superintendent or matron. In large hospitals, it would be advisable for the laundry, which should in all cases be in a building entirely detached, to be worked independently, under the general supervision of the governor or secretary.

Chaplain.—The religious care of the patients is generally provided for by the appointment of one or more permanent chaplains, or by visits and religious services of other ministers from the

patients may desire to attend them; subject, however, to the opinion of the medical attendant, as to how far the state of health of the patient will admit of such visits, and to the visits being made at such times as do not interfere with the discipline of the hospital.

DOUGLAS GALTON.

HOSPITALS, Construction of.—A hospital or infirmary is a building intended for the reception and treatment of sick and injured persons, under conditions favourable for their recovery.

A hospital must be so constructed and arranged as to enable a limited staff of medical men, nurses, and assistants to minister to the necessities of a large number of sick, and to promote their speedy restoration. The conditions essential for such objects are as follows:—

(1) *Pure air.* There should be no appreciable difference in purity between the air inside the wards and that outside the building.

(2) The air supplied should be capable of being warmed to any required extent.

(3) *Pure water* should be supplied for internal use, and sufficient also to ensure the removal of impurities to a distance from the hospital.

(4) The most perfect cleanliness within and around the building should be enforced.

These conditions depend on—

(1) *The site* of the proposed hospital.

(2) *The form* of the rooms or wards in which the sick are to be placed, so as to ensure purity of air and convenience of nursing, these rooms forming the principal units of hospital-construction.

(3) *The distribution* of these units, and of the other accessories, which combined constitute the hospital.

1 Sites of Hospitals.—The local climate should be healthy, and there should be a free circulation of air over the district. Town sites should be avoided as far as possible. When necessarily placed in a town, a space free from buildings should be reserved on all sides. There should be no nuisances, damp ravines, muddy creeks, undrained or marshy ground, near the site, or in such a position that the prevailing winds would blow effluvia arising from them over the hospital. The site selected for a hospital should not receive the drainage of higher ground, and the natural drainage outlets should be sufficient. There should, if possible, be no buildings near a hospital except those connected with its object. The number of sick to be allowed per acre will depend practically upon the arrangement of the buildings in which they are lodged.

2. Form and Distribution of the Parts of a Hospital.—The structural arrangements of a hospital should be such as to secure free circulation of air.

THE WARD.—The basis upon which the structural arrangements rest is the ward. The administration, means of access, and discipline must be made subsidiary to the question as to

* This article has reference more especially to permanent general hospitals. The principles apply equally to special temporary field or other institutions for the care of the sick.

how the sick are to get well in the shortest possible time, and at the least expense; and this, so far as the structure is concerned, is mainly determined by the form of the wards.

Size.—The size of a ward depends upon the number of patients which it should contain, and upon the cubic space and floor space which should be allotted to each patient. The disciplinary and economical dispositions in a hospital require that each head nurse should have the patients allotted to her placed under her immediate eye. Economy of labour requires that the hospital should be so laid out as to enable the largest number of patients to be nursed by a given number of nurses. The number to be placed in a ward therefore depends upon the number which can be efficiently nursed, and the form of the ward must be as much calculated to facilitate nursing, as to ensure free circulation and change of air. From twenty to thirty-two beds have been taken as the unit for ward-construction. In hospitals where cases of more than ordinary severity are likely to be received, it would be necessary to diminish the size of the wards on grounds of health. Small wards containing one or more beds are also required for isolating certain cases or for various necessary objects.

Form of ward-construction.—The general form of ward-construction is mainly governed by the question of the renewal of air. The air within an inhabited space, enclosed on all sides, is vitiated by the emanations proceeding from the bodies of those who inhabit it, and especially by the effect on it of their respiration. In all sickness, and all surgical cases wounds with discharge, or sores, these emanations are greater in quantity, and more poisonous in quality, than from persons in health, whilst, at the same time, most cases—medical and surgical—are more susceptible to these emanations. Stagnation in the movement of the air leads to rapid decomposition of these emanations. If they diffused themselves uniformly throughout the space which in fact they do not, ventilation would be comparatively simple, and, whatever the cubic space, the air would attain a permanent degree of purity, or rather impurity, theoretically dependent upon the rate at which emanations are produced, and the rate at which fresh air is admitted. Hence the same supply of air would equally well ventilate any space, but the larger the cubic space, the longer it will be before the air in it attains its permanent condition of impurity, and the more easily will the supply of fresh air be brought in without altering the temperature, and causing injurious draughts. The amount of air which should be removed, and its place supplied with fresh air, is at least 3,000 cubic feet per patient per hour, but this must depend to some extent upon the emanations of the patients, which vary with the diseases or injuries they are suffering from. The ventilation of each ward should be kept independent of other wards or rooms.

Means of ventilation.—The change of air may be effected in various ways. For instance, the air may be drawn out by a fan, or it may be removed by a shaft, whose action depends on the difference of the temperature of the air in

the shaft and that in the outer atmosphere. Of this the ordinary fireplace is one example, a caldron of water kept boiling for the use of the hospital by a steam pipe is another, a sunlight is a further example, and a heated shaft connected with fines led from holes in the wall near the patients' beds through each of which air is drawn into the shaft, is another method. Theoretically it is thus quite possible so to arrange the ventilation mechanically that a specified quantity of air at a fixed temperature shall be brought into the ward by day and by night. Practically, however, hospitals dependent upon such means alone for ventilation, require an attention which they can rarely or never receive, and, except under favourable circumstances, are not healthy.

The emanations from the body do not uniformly diffuse themselves, they hang about as the smoke of tobacco may be said to do. In wards into which a fixed quantity of air is forced, there is not even a uniform degree of impurity, consequently it is necessary, in order to ensure the purity of the air of a ward, that means should exist for absolutely sweeping out at intervals all the impure air from it, and starting afresh with pure air. This is best effected by the direct action of currents of fresh air brought in by open windows placed on opposite sides of the wards. The distance between windows for this purpose must not be too great to prevent their efficient action in moving the air. Twenty-four feet is a good width, but opposite windows for such an object should in no case be more than from thirty to thirty-five feet apart. The space between the windows should not be obstructed by walls or partitions. The number of patients—that is to say, the sources of impure emanations—placed between opposite windows, should be limited to two rows. In the daytime, and when the weather admits of open windows, a ward with windows opening on both sides can easily be kept fresh, but for other seasons it is necessary to provide openings for the escape of impure air, and for the admission of fresh air which shall not cause draughts.

For the purpose of removal of air, shafts carried up from near the ceiling-level to above the roof are convenient, the lower ends being lowered to prevent patients feeling draughts which may occasionally prevail. The most powerful engine of ventilation for drawing out the air is an open fire-place.

In order to prevent the temperature of the ward from being lowered by the extraction of air, that is, to maintain an equable temperature, and to prevent draughts, air warmed to a moderate degree should replace that removed by the fireplace or by other openings. Means for the admission of air in an upward current should be provided direct from the open air, independent of the windows and doors, for this purpose tubes with bends, which favour the collection of dirt, are objectionable. Sherringham's ventilators, which are easily cleaned, placed between the windows near the ceiling answer well, they admit the air without perceptible draught, and also frequently act as outlets when open on the leeward side of a ward. The external air may be warmed as it enters by being made to pass over hot-water

or steam pipes. Openings, if placed close to the floor under the beds, should be capable of being easily and securely closed. All openings for the admission of fresh air should be so placed as to be easily examined and cleaned throughout their whole length, and this should be done at least once a year.

Superficial area.—The next most important element in the question of ward-construction is the superficial area to be allotted to the patients, which is even more important than cubic space, for on this depends the distance of the sick from each other, the facility of moving round the sick, shifting beds, cleanliness, and other points of nursing. If there be a medical school attached to the hospital, the question of area has to be considered with reference to affording the largest amount of accommodation practicable for the teacher and his pupils without their breathing up the patients' air. A ward with windows improperly placed, so as not to give sufficient light, or where the beds are so placed that the nurse must necessarily obstruct the light in attending to her patients, will require a large floor-space, because the bed-space must be so arranged, and of such dimensions, as to allow of sufficient light falling on the beds. In well-constructed wards with opposite windows, the greatest economy of surface-area can be effected, because the area can be best allotted with reference both to light and to room for work. In a ward 24 feet in width with a window for every bed or every two beds, a 7 ft. 6 in. bed-space along the walls would probably be sufficient for nursing purposes. This would give 90 square feet per bed, and there should be as little reduction as possible below this amount for average cases of sickness, but this space is much too small for surgical, fever-, or lying-in wards, which should also be for a much smaller number. The Herbert Hospital, without a medical school, has 99 superficial feet per bed; St. Thomas' Hospital, with a medical school, has 120 superficial feet per bed. The bed-space should be larger if the locality is less healthy.

The area allotted to patients practically settles the cubic space, because wards should not be less than 12 feet high, though as a rule they need not exceed 11 feet in height.

In a good situation, and for ordinary cases of disease, those spaces which are enough for nursing and for ward-administration would, with good ventilation, be sufficient for all sanitary purposes, but for such cases as typhus or other epidemic diseases, operations, and bad surgical diseases, a larger space and area would be required. When severe cases of this class come into an ordinary hospital, the simplest plan is to leave the bed vacant adjacent to that occupied by the patient.

Lying-in wards should never contain more than from one to four beds. In recent French hospitals these wards contain one bed each, and the only access to them is from an open verandah and through a small ante-room. Ovariotomy, and other operations of the highest risk, should be performed in a one-bed ward. When space permits, a room may be provided for the use of patients when convalescent, and able to be temporarily absent from the ward. The same

observation applies to grounds for outdoor exercise. But separate convalescent hospitals or homes are better, both for health and discipline. If hospitals are provided for special infectious diseases, every patient should be placed in a separate hut-ward. Cleanliness and abundance of fresh air is the best safeguard against infection.

Materials.—With a view to economise heat in winter, and to keep the rooms cool in summer, the walls should be hollow, and all walls should be ceiled unless the roof is constructed of a good non-conducting material. The best lining for a hospital-ward would be an impervious polished surface, which on being washed with soap and water, and dried would be made quite clean. Plaster, wool, paint, and varnish all absorb the organic impurities given off by the body. Parian cement polished is the best material at present known for walls, but it is costly and it can only be applied on brick or stone walls, and not on woodwork, because, being inelastic, it is liable to crack. Cracks in a hospital ward are inadmissible, as they get filled with impurities, and harbour insects. The numerous joints required for glazed bricks, or tiles, render the use of these questionable for wards. In default of Parian cement, the safest arrangement is plaster lime-whited or painted, which should be periodically scraped, and be then again lime-whited or painted.

The floor should be as non-absorbent as possible, and for the sake of warmth to the feet it must in this country be of wood. Oak, or other close hard wood, with close joints, oiled and beeswaxed, and rubbed to a polish, makes a very good floor, and absorbs little moisture. The joints should be like those of the best parquet-terie, affording no inlet for dirt. There should be no sawdust, or other organic matter subject to decay, under the floor. When a ward is placed over another, it is essential that the floor should be non-conducting of sound, and that it should be so formed as to prevent emanations from patients in the lower ward passing into the upper wards. Practically, with care, a well-laid oak floor, with a good beeswaxed surface, can always be kept clean by rubbing.

There should be as little woodwork as possible in a ward, besides the floor, and what woodwork there is should be varnished, so as to admit of easy washing and drying. The cleanest and most durable material is varnished light-coloured warmst oak or teak.

The form of the windows must be considered, in their aspect of affording light as a necessary means of promoting health, of affording ventilation, of facilitating nursing, and of enabling the patients to read in bed. Light can always be modified for individual patients. In order to give cheerfulness to the wards, and to renew the air easily, the windows should extend from within 2 feet or 2 feet 6 inches from the floor—so that the patients can see out—to within 1 foot from the ceiling. An end window to a long ward is an element of cheerfulness, and materially assists the renewal of the air at night. It is essential to cleanliness that every part of the ward should be light. One superficial foot of window-space to from 50 to 55 cubic feet of space, will afford a light and cheerful room, but

this depends much on aspect and upon the walls being light-coloured. To economise heat in wards, it is desirable to make the windows of plate glass; double windows of ordinary glass would secure the same object and facilitate ventilation, but they are troublesome to clean, and give a gloomy appearance to a room. The best form of sash for ventilation in this climate is the ordinary sash, opening at top and bottom, but windows made in three or four sections, each of which falls inwards from an axis at the bottom of the section, possess many advantages for hospitals.

Ward offices.—The Ward offices are of two kinds:—

1. Those which are necessary for facilitating the nursing and administration of the wards, as the head-nurse's room and ward-scuttery.

2. Those which are required for the direct use of the sick, so as to prevent any unnecessary processes of the patients taking place in the ward; as, for instance, the ablution-room the bath-room, the water-closets, urinals, and sinks for emptying slops. There should, in addition to the bath-room here mentioned, be a general bathing-establishment attached to every hospital, with hot, cold, vapour, sulphur, medicated, shower, and douche baths. Hot and cold water should be laid on to all ward-offices in which the use of either is required, because of the economy of labour in the working of the hospital. For the same reason, when the wards are on two or more floors, lifts should be provided to carry up coals, trays, and patients. The ward-offices should have ample window-space. There should be no dark corners or closed spaces under sinks. Nothing should be kept in these offices which is not in constant use, and everything in use should be open to inspection. All fittings should be light-coloured, so as to show dirt.

1. The *head-nurse or sister's room* should be sufficiently large to contain her bed, and to be also her sitting-room. It should be light, airy, and well-ventilated. It is necessary to discipline that it should be close to the ward door, and that it should when practicable have a window looking into the ward. If the head-nurse has two wards to supervise, her room should be placed between the two, with a window opening into each.

There should be a *ward-scuttery* to each ward, and so situated as to be under the head-nurse's eye. The scuttery should be supplied with efficient, simple apparatus for its purposes, there should be a small range for ward-cooking, so that the nurse can warm the drinks, prepare fomentations, &c. Shelves or racks should be provided. There should also be a small larder, with free circulation of air, for temporarily keeping provisions fresh. In the scuttery, or adjacent to it, a hot closet should be provided for airing clean towels and sheets. Foul linen should not be retained near the wards, or in the hospital building. It should all be placed in baskets, on wheels, and conveyed as soon as possible to the laundry. Ward sweepings and refuse should similarly be placed in movable receptacles, and taken out of the building with as little delay as possible; structural provision for the retention of these in or near the hospital is undesirable.

2. The *ablution-room, water-closets, &c.*, ought to be as near as possible to the ward, but cut off from it by a lobby, with windows on each side, having its ventilation and warming distinct from that of the ward and that of the ward-offices, so as to prevent the possibility of foul air passing from the ward-offices into the wards. The ward-offices will be most conveniently placed at the end of the ward farthest from the entrance and nurses' room; and distributed at each side, so as to enable the ward to have an end window. In this arrangement the ablution-room would be on one side of the ward, and should contain a small bath-room with a fixed bath of copper, supplied with hot and cold water. A lavatory table of impervious material, such as slate or common marble, with a row of sunk porcelain basins with outlet tubes and plugs, each basin supplied with hot and cold water, should be placed in the same compartment as the bath, but separated from it by a partition and door. There should also be room for a portable bath for each ward, and there should be a sink on the floor level for running off the water from the bath after it has been used.

On the other side of the end window of the ward would be placed the *water-closets*. These should never be against the inner wall, but always against the outer wall of the compartment in which they are placed. A pan of a hemispherical shape, never of a conical shape, with a syphon, abundantly supplied with water to flush it out all round with a large forcible stream, is the best contrivance for the water-closet of a hospital. The urinal should be of a shape to be easily cleaned. The sink for slops, bed-pans, expectoration-cups, &c., which should have a compartment of its own adjoining the water-closets, should be a large, deep, round, pierced basin of earthenware, with a cock extending far enough over the sink for the stream of water to fall directly into the vessel to be cleaned, and with an ample supply of water in a full stream, this sink should be so arranged as to be flushed out like a water-closet pan, and it should be so placed as to make it unnecessary for male patients to pass the nurse on their way to the w.c. There should be a special receptacle near the sink, vented to the outer air, for keeping chamber utensils, &c., for the examination of the medical officer.

Walls of ablution-rooms and water-closets should be covered with white glazed tile, slate (enamelled or plain), or Parian cement; plaster is not a good covering for them on account of their liability to be splashed, and of the necessity for their being frequently washed down. There should be separate private water-closets for the nurses, and also water-closets for the patients when in day-rooms or recreation-grounds. The ablution-room and water-closets should be supplied with plenty of fresh air, warmed when necessary, and abundance of light, so as to ensure there being no dark corners. Three water-closets per ward will suffice for a ward of thirty-two beds, but two at least will be required for even a twelve-bed ward.

The water supply should provide, in addition to pure water for general consumption, a service

of distilled water for dressings and suchlike purposes.

3 **Aggregation of Ward-Units in the Construction of a Hospital.**—The principles upon which these units of hospital-construction, or, as they are generally termed, pavilions, when so constructed, should be aggregated, are as follows:—

(1) There should be free circulation of air between the pavilions.

(2) The space between them should be exposed to sunshine, and the sunshine should fall on the windows, for which purpose it is desirable that the pavilions should be placed on a north and south line.

(3) The distance between adjacent pavilions should not be less than twice the height of the pavilion reckoned from the floors of the ground-floor ward. This is the smallest width between pavilions which will prevent the lower wards from being gloomy in this climate, where there is not a free movement of air round the buildings, this distance should be increased.

(4) The arrangement of the pavilions should be such as to allow of convenient covered communication between the wards, without interfering with the light and ventilation, and therefore the top of the covered corridor uniting the ends of pavilions should not be carried above the ceiling of the ground-floor wards. Each block of wards, that is, each pavilion, should have its own staircase.

(5) No ward should be so placed as to form a passage room to other wards.

(6) As a general rule, there should not be more than two floors of wards in a pavilion. If there are three floors or more the distances between the pavilions become very considerable because of the rule already mentioned, which ought to be absolutely observed, which regulates the distance at which the pavilions must be kept apart. Besides, when two wards open into a common staircase, there is, with every care, to some extent a community of ventilation; this will prevail even if the staircase be furnished with permanent openings to the outer air. When there are as many as four wards one over the other, the staircase becomes a powerful shaft for drawing up to its upper part, and thence into the ward, the impure air of the lower wards. Similarly, heated impure air from the windows of the lower wards has occasionally a tendency to pass into the windows of the wards above. For the same reason the upper floor over the wards should not be used as a dormitory for nurses. Similarly if there is a basement under sick wards, it should not be used for any purpose, such as cooking, or for the reception of perishable stores from which smells could penetrate into the wards, and it is best not to continue the staircase into the basement, for with every care the basement will always form a receptacle for ground air, which should be kept out of the hospital if possible.

There is a limit to the numbers which should be congregated under one roof. This limit will depend very much on the nature of the cases. In town hospitals, a double pavilion should not contain above 80 to 100 beds.

The size of any given hospital ought not to be

determined by increasing the number of beds in any one building, but by increasing the number of units or wards. So far as the sick are concerned, they would be better placed in single detached wards, or, for convenience of administration, in wards all on one floor—opening out of a common corridor. But on town-sites the cost of land makes it absolutely essential to build hospitals as compactly as possible; moreover economy in the current expenses will be best secured by a building with wards on two or more floors, provided with lifts and other labour-saving appliances.

In addition to the larger wards, it is necessary, as already stated, to have a few wards of one or two beds each for special cases.

Corridors should connect the pavilions on the level of the lower floor of wards only. They should be kept as low as possible, so as not to impede the circulation of air between the pavilions; they should be lighted by windows on both sides, opening widely, or removable in warm weather, and they should be provided with ample means of ventilation and with fresh warmed air in cold weather, so as to prevent draughts.

The staircases should be treated similarly as to light and ventilation, and it is desirable to cut off the connecting corridors from adjacent staircases by swing-doors. These arrangements prevent draughts, and cause the passages and staircases effectually to cut off the ventilation of one pavilion from that of another.

The staircases for patients should be broad and easy, the rise of each step should not exceed four inches in height, and the tread should be at least one foot in width, there should be a handrail on each side, and a landing after every six or eight steps provided with seats. The patients in their beds may be wheeled on to the roof of the corridors between the pavilions, or on to a broad balcony outside the end window of the ward, in fine weather.

4 **Administrative Buildings.**—The necessary subsidiary accommodation may be briefly described.

Operating rooms, dispensary, and school.—These should include examining room, surgery, drug store, and operating theatre; the latter having roof-light from the north, and being of easy access to the surgical wards, there being one theatre for male, and one for female patients. Special wards for such cases as ovariotomy should contain but one bed. A dead-house and post-mortem room, with ample means of cleanliness, should be provided, quite outside, and detached from the hospital. Where a school is to be established, the necessary lecture-rooms, laboratories, dissecting-rooms, &c. should be kept entirely separate from the building for the sick.

All rooms should be plain, and without projections or ornaments, which form a resting-place for dust.

Officers' quarters.—Apartments for the resident physician and surgeon, matron, nurses, and servants should not, if practicable, be placed under the same roof with the sick. All the rooms should be light and airy. The resident physicians and surgeons should have each a bed-room and sitting-room, with proper convenience adjacent; and a dining-room for joint use.

The dispenser, if resident, requires a bed-room and sitting-room. An office is required for the steward (purveyor or financial officer); and a room for meetings of the governing body. Each ordinary nurse should have a separate bed-room; neither bare, tarnished, nor dismal; where she may obtain pure air while she sleeps—the night nurses' bed-rooms being apart, where they may not be disturbed by noise. There should be bath and closet accommodation near; but women should each be allowed a washstand and foot-bath in their own room. The head-nurse or 'sister' sleeps in her own room, overlooking her ward; but if there is no common-room, she would have better health if a small sitting-room, as well as bed-room, could be given her off her ward. The head-nurses or 'sisters' should have a dining-room, and also a comfortable well-furnished sitting-room. They will work better in their wards if they themselves are made comfortable. For sisters and nurses now-a-days are, or ought to be, educated women. It is most undesirable that they should seek necessary amusement all out of doors. Nurses should dine in the sisters' dining-room, but at a different hour; and in a large hospital there would probably be required an additional dining-room for ward-assistants. In hospitals with an establishment for training nurses, which every large hospital ought to have, the probationers or pupil nurses (in a proportion not exceeding one to every ten or twelve patients) would live in a 'home' under the hospital roof, and under the direction of the hospital matron.

The 'Home' should consist of—1. Class-room and nurses' library, large, airy, and convenient. 2. One or two dining-rooms, in which sisters and nurses might also dine, and pantry adjoining. 3. Two rooms and an office for the 'home sister' (class mistress). 4. One separate bed-room for each probationer, sufficient to contain press, table, chair, book-shelf, washstand, bedstead, and arm-chair.

Each floor should have a bath-room and other conveniences. Bed-rooms for probationers on night-duty should be cut off from the noise of the 'Home.' There should also be provided—one sick room; one visitors' room; and servants' offices and bed-rooms for cook and other necessary servants.

Stores for bedding and linen, kitchen and provision stores.—The kitchen and all those stores between which and the wards there is a constant movement, should be as central as possible, so as to save labour; but the kitchen should be carefully cut off from the corridor connecting the pavilions. Attached to the kitchen should be a good scullery, larder, and serving conveniences. There should be a large, well-aired, well-lighted, well-warmed, well-arranged linenry and mending room. The hospital laundry should be detached from the hospital. Special care should be taken to make the laundry buildings airy and very light, with ample means of ventilation for removing the steam, which is heavily charged with organic impurity, and with ample space for the washers. They should have separate drying and ironing rooms.

Out-patients' department.—Those hospitals which afford out-door relief require a dispensary

for out-door sick. This should always have an entrance separate from the hospital, and should never be under or near a ward, or in the space between adjacent wards. It is placed in proximity to the hospital, for the convenience of the medical men, and medical school (if any), and in order to be near the drug-store and apothecary's shop; but it should be entirely detached, with a free air-space between, and no direct communication be possible.

The out-patients' department requires a large airy waiting-room, with separation of sexes, and separate closet accommodation for males and females, which, without great care, may (even when detached) become a nuisance to the sick wards; a consulting room for each of the physicians and surgeons, to which should be attached a small lavatory and all necessary conveniences for the complete examination of patients. The out-patients' department of Children's Hospitals requires more care, and more ample space in waiting-rooms, because each patient is brought by its nurse. The entrance and exit should be through different doors.

In every large hospital should be provided a well-ventilated chapel, capable of being well warmed.

The position and general construction of the administrative buildings should be made quite subservient to the accommodation for the sick, and to the broad general principle that these buildings should not interfere with the circulation of the air round, or the light of, the wards.

DOUGLAS GALTON.

HUM, VENOUS—A continuous murmur heard in the veins, generally observed in cases of anemia. See ANÆMIA; and PHYSICAL EXAMINATION.

HUMID (*humidus*, moist).—Moist—in contradistinction to *dry*. Applied to râles (see PHYSICAL EXAMINATION), to characterise a variety of asthma attended with expectoration (see ASTHMA); and also to particular climates. See CLIMATE.

HUMORAL (*humor*, a humour).—Of or relating to the humours. Chiefly used as a term for a pathological doctrine—the *humoral pathology*—which associates all diseases with morbid states of the fluids of the body (see BLOOD-DISEASE). The word is also sometimes employed as synonymous with *humid*, when applied to asthma.

HUNYADI JÁNOS, in Hungary. Sol-planted waters. See MINERAL WATERS.

HYDATIDS (*idæris*, a drop of water).—**SYNON.**: Fr. *Hydatide*; Ger. *Blasenwurm*.

GENERAL REMARKS—This term is now restricted to those bladder-worms which are larval forms of the so-called *Tenia ochrosporocœna*—a minute tapeworm residing in the dog and wolf. Formerly all the bladder-worms were apt to be spoken of as hydatida, and thus we had the *Hydatia cellulosa*, *H. erratica*, *Hydatigema granulosa*, and so forth. They were also frequently called *acrophocysts*, and thus, following Lænnec, we had the *Acrophocystis granulosa*, *A. cæcæna* and *endogrua* of Kuhl and John Hunter, *A. sicca* of

gers, &c. *Again, they were as often characterised as various species of *Echinococcus*, whence we had the *Echinococcus hominis*, *E. veterinarius*, *E. polymorphus*, *E. granulosa*, and so on. At length, all these numerous forms of hydatid were reduced to a very few types, and now we are all agreed that there is only one true larval species, although it is liable to assume a practically endless variety of shapes.

That the minute tapeworm (*Tenia echinococcus*) is really the sexually mature condition of the ordinary hydatid, as known to physicians and surgeons, was first experimentally proved by Naunyn, who, in 1864, fed two dogs with liver hydatids, previously ascertained to contain heads (*accolers*). The first dog, destroyed twenty-eight days afterwards, yielded a negative result; but the second dog killed thirty-five days subsequent to the feeding, contained numerous examples of *Tenia echinococcus* in the sexually mature condition.

By feeding dogs with fresh and perfectly formed hydatids we have thus obtained the minute tapeworm which selects for its abode the upper part of the small intestine. Conversely, hydatids may be reared by feeding animals with the eggs of the *Tenia echinococcus*. It appears that the formation of all true hydatids, whether developed in mankind or in animals, results from the ingestion of the tape-worm eggs. The eggs may be swallowed either with food or drink. In this way, impure water is doubtless the most common source of hydatid disease. All open waters, if dogs abound in the neighbourhood, are liable to be contaminated with the fatal germs. The careless drinking of unfiltered or insufficiently filtered water may lead to hydatid infection.

The formation of hydatids after the eggs have been swallowed, is a very slow process. What we know on this point is principally due to the researches of Leuckart; but our knowledge of the intimate structure of the perfected organism, as such, has been very carefully worked out by a number of observers, amongst whom, after Leuckart, stand the names of Rasmussen, Naunyn, Heller, Von Siebold, Eschricht, Wagner, Kuchenmeister, Erasmus Wilson, Busk, and Huxley. In this connection also, particular mention must be made of the researches of Vercow, who was the first to make us acquainted with the true nature of the multilocular form (*Echinococcus multilocularis*) which has also been investigated, amongst others, by Luschka, Leuckart, and Heller. In the more purely pathological and statistical aspects of the subject, the writings of Rokitsansky, Schleissner, Wunderlich, De Haen, Kräbe, Klencke, Livois, and Davaine hold a conspicuous place; whilst clinically we have space only to particularise the memoirs of Murchison, Hegbie, Clegghorn, Macgillivray, Robertson, Dougan Birl, and especially Hoern (*Kystes Hydatiques du Foie*; Paris 1875). From the above statement, it will readily be understood that the literature of the subject is of very great extent; but those who desire an exhaustive knowledge of the subject should also consult Dr Albert Neisser's admirable compilation (*Die Echinococcenkrankheit*; Berlin, 1877). In this place it is only intended to offer a brief account

of the general structure of hydatids, with a résumé of the facts of their distribution and prevalence in particular countries, and their occurrence in the organs of the body selected for residence. Remarks on treatment and on the hygienic bearings of the subject will fitly close the article.

DESCRIPTION.—Pathologists recognise three varieties of hydatid, namely, the exogenous, endogenous, and multilocular. The first of these is sparingly found in man, but very common in the lower animals. The second is rare in animals, but frequent in the human subject. The third variety is found in man, very rarely, Professor Bollinger having also found it in the liver of a calf (*Deutsch Zeitsch f Tiermed.*; 1876). The precise mode of origin and growth cannot be discussed here. Practically, it is of little moment which of the various hypotheses we accept; nevertheless the subject is of the highest interest when viewed from a physiological standpoint. Whilst there is rarely any difficulty in determining the character of ordinary hydatids, whether of the exogenous or endogenous kind, the multilocular form is very apt to be overlooked or misinterpreted. It has been mistaken for alveolar colloid, with which latter product, as remarked by Vercow, it has nothing whatever in common. There is reason to believe that some of the so-called examples of cirrhosis of the liver are neither more nor less than multilocular hydatid growths. Professor Heller, of Kiel, has called our attention to several preparations in the London Museums, which he thinks may be of this order, but the writer has not found opportunity to examine them microscopically. Condensing Leuckart's description, which we have ourselves verified from the examination of a specimen kindly supplied by Heller, it may be said that the essential characters of this growth are marked by a tough, well-defined fibrous limiting capsule, consisting of a dense stroma, whence bands of connective tissue pass off in every direction, penetrating the entire growth, and leaving small interstices. These interstices or alveoli are irregular in shape, lined with vesicles that are filled with a gelatiniform plasma, occasionally containing also the so-called echinococcus-heads. Here and there small blood-vessels may be seen, and also collapsed bile-ducts, but no trace of any true glandular parenchyma of the organ affected.

Ordinary hydatids, whilst presenting variable shapes according to the nature of the organ occupied, commonly exhibit a thick investing capsule derived from the tissues of the infected part. Within this capsule or cyst we first come upon a thick, homogeneous, laminated, elastic membrane, which, if withdrawn, displays a peculiar tremulous motion, coiling upon itself wherever it happens to be divided by the scalpel. This is the so-called cuticular, structureless layer, or *ectocyst* of Huxley. Within this outer layer, and closely applied to it, lies the delicate *endocyst* of the same authority. This is a thin, soft, comparatively non-elastic, granulated membrane, forming the essentially vital part of the bladder-worm. From this inner membrane buds are produced, and these gemmæ become transformed into echinococcus-heads both in a direct and

indirect manner. Commonly they form broad capsules containing numerous heads, some of which, by a process of eversion, may be seen

FIG. 24. Hydatid of four weeks' growth, showing ectocyst and endocyst. $\times 60$ After Leuckart.

projecting into the general cavity of the mother-hydatid. At other times by a process of what is termed proliferation, daughter and even grand-daughter hydatids are formed within the

FIG. 25. Group of Echinococci, with their hook-crowns inverted. $\times 180$ diam. After Busk.

original maternal hydatid, and these smaller hydatids (constituting an agamogenetic bladder-worm progeny) in their turn produce echinococcus-heads within them. The precise mode

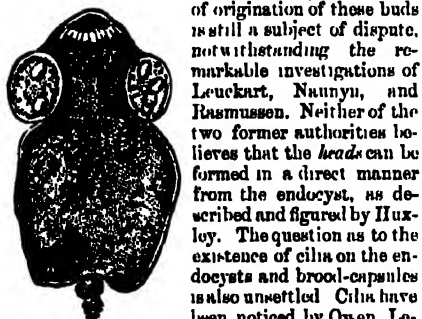

FIG. 26. The so-called *Echinococcus head*, showing hooks, suckers, cilia, and corpuscles. $\times 240$ diam. After Huxley.

of origination of these buds is still a subject of dispute, notwithstanding the remarkable investigations of Leuckart, Naunyn, and Rasmussen. Neither of the two former authorities believes that the heads can be formed in a direct manner from the endocyst, as described and figured by Huxley. The question as to the existence of cilia on the endocysts and brood-capsules is also unsettled. Cilia have been noticed by Owen, Lobert, and Whittell. These various authorities aver that they occur outside the so-called echinococci. Huxley looks upon them as having a connection only with the water-vascular system, whilst Leuckart entirely failed to detect them anywhere. We are not here called upon to

pursue this part of the subject further, but may remark in passing that the little sacs now termed brood-capsules by Leuckart and others were well known to Erasmus Wilson, who figured them in 1845, and also to Busk, who previously spoke of them as 'granulations' (1844).

Occurrence.—The prevalence of hydatids in any country bears a strict relation to the degree of intimacy subsisting between its inhabitants and the dogs employed by them for domestic purposes. If in this respect Iceland holds pre-eminence, the explanation is not far to seek. As remarked by Krabbe, it is not necessary to suppose that the Icelanders actually devour the excrement of dogs, although, to be sure, canine faeces, according to Schleimer, figure amongst the remedial agents employed by quacks and empirics. It is sufficient for the purpose of infection that the natives and their dogs share the same habitation, that the animals are fondly caressed, that they feed off the same plates (which they are often encouraged to lick clean, in order that their masters may be spared the trouble of having them washed), and that they sleep with the peasants in the same bed. Thus, as Krabbe says, either through carelessness, ignorance, or indifference on the part of the natives, the eggs of the hydatid-forming tapeworm have abundant opportunity of gaining access to the human bearer. To a certain extent, as Krabbe observes, this close relationship and high degree of infection are forced upon the poor people by the rigours of the climate, and insufficient resources of the country. Nevertheless, it is clear that a very large amount of echinococcus-disease exists in countries where there is comparative freedom from these disadvantages. The circumstance that the germs are far too small to be seen by the naked eye, and that they may be distributed by various possible agencies (long after they have either been passed with the faeces, or have been dispersed by the semi-independent and sexually ripe proglottides), is alone sufficient to ensure infection, provided the necessary sanitary precautions are not adopted. Open natural waters, however pure and sparkling they may look, are apt to contain hydatid germs in all countries where dogs abound. Thus it is that cattle become infected, not alone indeed by drinking foul water, but also by grazing in districts where the eggs of the *Tænia echinococcus* are dispersed by winds, rain, and even insects flying away from the germ-infected fecal matter on which they had previously settled for repast. Of course, direct contact with infested dogs renders infection almost a matter of certainty. Anyone who has witnessed the migration of tapeworm proglottides on the surface of the bodies of cats and dogs, will readily understand how it comes to pass that the mere act of coaxing a dog's back is sufficient to convey numerous germs to the hand, whence they may be transferred to the lips and mouth of the human bearer. It is fortunate, indeed, that in European countries our *Tænia echinococcus* is comparatively rare in the dog. But for this circumstance, hydatids might become almost as prevalent amongst the peasantry of our own country as they are known to be in Iceland. Probably the next most infested territory is that of Victoria (Australia). On this

print the writer has collected much convincing evidence; recently confirmed by Dr. David Thomas, of Adelaide. According to one local authority, not only has the disease been more or less prevalent in the Victoria colony for many years past, but it is 'greatly on the increase in the human subject'. It would be easy to multiply statements bearing out the same truth, but the subject is too special for detailed treatment, and it has been dealt with, at some length, in the writer's general treatise (*Parasites*, London, 1879). Those, also, who desire to obtain a general notion of the frequency of hydatids in England would do well to reflect upon the amount of collateral evidence supplied by the numerous specimens preserved in the museums of the metropolis and elsewhere. In the face of facts, patent to all, it must be obvious that the amount of hydatid disease now existing everywhere, is susceptible of being greatly diminished by the introduction of appropriate sanitary regulations. In what these regulations consist may be readily gathered from the circumstances connected with infection. To some extent, Iceland has already moved in the matter, following the counsel of Dr Kralbe.

SITUATIONS.—The relative prevalence of hydatids in particular organs of the body is a matter of great concern, clinically and hygienically. The writer has been at some pains to open up this subject, and from the data collected independently by Davaine and himself, the results obtained may be relied on as approximately correct. Reduced to the lowest number of practically available or useful terms, our statistics stand as follows:—

Organs affected.	Davaine.	The writer.	Total.
Liver	165	161	326
Abdomen, pelvic cavity, and spleen	26	45	71
Lungs	40	22	62
Kidneys and bladder	30	23	53
Brain	20	22	42
Bones	17	16	31
Heart, and pulmonary vessels	12	13	25
Miscellaneous	63	25	92
Grand total	373	327	700

Notwithstanding certain apparent differences, the results separately obtained by Davaine and the writer show a remarkable correspondence. Thus, in the case of those organs respecting which no dispute could well arise as to the real seat of the disorder, the results are tolerably uniform. This is seen in the case of the liver, brain, heart, and bones. Even in those instances where the results do not appear to correspond, the explanation of the discrepancies is very simple. One example will suffice to illustrate this point. The twenty-six abdominal cases credited to Davaine's record are all placed by him under the heading of 'Pelvis,' whilst all those cases placed by the writer under the abdominal series not only include hydatids of the pelvic cavity, but also two from the spleen and nineteen from the peritoneum and intestines, besides others.

As the facts thus stand, it is instructive to notice that the liver cases comprise nearly 46½ per cent. Comparatively recent computations

by Dr. Albert Neisser, based on 983 cases, afford a percentage of 45·766 for liver cases. It is especially worthy of remark also that no inconsiderable proportion of the bladder-worms occupy organs of vital importance to the host. If, in reference to sanitation, statisticians would obtain an adequate conception of the cause of the fatal power of hydatids, they should look close into this matter. Let them note the fact that in 6 per cent. of all the cases collected by Davaine and the writer the entozoon occupied the brain; in about 3½ per cent. they took up their residence in the heart, and probably in not less than 15 per cent. of all the other cases they operated to bring about the death of the human bearer. The writer is of opinion that (excluding the cases cured by surgical interference) the echinococcus-bladderworm proves fatal to 25 per cent. of all the human victims it attacks. Animal-bearers, on the other hand, comparatively rarely succumb to hydatid invasion. (For further details see *Lancet*, Jan 19, 1875, p. 880; *British Medical Journal*, 1875, and the writer's treatise on *Parasites*, 1879, pp 121-141.)

DIAGNOSIS.—Many cases of hydatids present extreme difficulty in respect of diagnosis, especially those occupying the cavity of the chest. To diagnose hydatids of the brain, heart, and kidneys is rarely possible, unless very strict attention be paid to the symptoms, and to the conditions under which the patient has been living. In kidney cases, the escape of small vesicles with the urine, would, of course, help to decide the matter. In heart-cases it is rare that any premonitory symptom of the affection shows itself. Under ordinary circumstances, where these and certain other organs are out of the question, the presence of a fluctuating tumour, without any concomitant inflammatory symptoms, especially if it be seated in the region of the liver, would to most of us at once suggest the likelihood of the occurrence of an hydatid growth. Much has been said of Piorri's 'hydatid frmitus,' which, however, scarcely differs from the ordinary impulse communicated by fluid matter within any other kind of tumour. Speaking generally, the accidental discharge of one or more acrophocytes constitutes the most common and absolutely certain means of diagnosis. That these formations are frequently discharged by the natural outlets of the body is well known to every practitioner; and not unfrequently has the scalpel of the surgeon evinced them, when their presence was not so much as suspected by the operator. How constantly their presence within the viscera is altogether overlooked is a matter well known to every pathologist connected with our large hospitals.

TREATMENT.—The treatment of hydatid-disease may naturally be spoken of under three heads, namely, *surgical, medical, and prophylactic* or preventive.

Surgical.—With the first method we have of course little to do here, but in respect of diagnosis it is obvious that the surgeon must often require the assistance of the physician. In the matter of operative treatment, the writer has elsewhere taken occasion to comment, incidentally, upon the remarkable amount of success obtained by Dr. MacGillivray, at the Bendigo

Hospital. (See his records given from time to time in the *Australian Medical Journal*.)

Medicine.—As regards the success of medical treatment, the opinion long ago expressed in the writer's Introductory treatise still holds good (*Entozoa*, 1864, p. 285). As then stated, 'a great deal of nonsense has been written about the efficacy of particular drugs,' but, making allowance for the advantages secured by aspiration and electrolysis, we think that the words spoken by Dr. Todd in 1861, are still very near the truth:—'I know of no cure for hydatids but the evacuation of them. There is a popular notion that salt will kill the hydatid. Iodide of potassium has also been frequently tried, but I have never seen any real benefit from the use of these remedies.' Since Dr. Todd's time, the employment of several other drugs has been warmly advocated by different physicians, amongst whom the names of Dr. Leared, Dr. Hjaltehu, and Dr. Bird stand out most prominently. According to the two first-named observers *kamala* has the power of destroying hydatids. If, however, anyone will take the trouble to peruse Dr. MacGillivray's record of his efforts to obtain proof of the alleged curative properties of *kamala* when administered internally, they will at once perceive that this much over-praised drug has 'no influence whatever on the disease.' In like manner, the writer fears that the alleged virtues of turpentine in this respect, as advocated by Austrian practitioners, will turn out to be an entire mistake. It is all very well to speak of turpentine and certain other well-known anthelmintics as powerful teniafuges; but it is quite another thing to assert that these drugs can destroy bladder-worms by the ordinary mode of oral administration. As stated in the early part of this article, the essentially vital part of the hydatid is the granular endocyst, and to reach this the poison must not only penetrate the more or less dense capsule of connective tissue, but also the laminated ectocyst. If the advocates of *kamala* had reflected on the enormous quantity of the drug necessary to produce any sensible effect on the hydatid, they would probably not have attempted its employment. In like manner, notwithstanding what has been said of the power of turpentine, in respect especially 'of its property of accumulating in the system,' we must express ourselves as exceedingly sceptical as to the likelihood of turpentine being of any more curative value than *kamala* when prescribed internally. In regard to the successful employment of iodine and other drugs for the purposes of injection, after evacuation of the fluid contents of hydatid cysts, there can be no doubt as to the good results frequently obtained, nevertheless, as M. Boinet and others long ago pointed out, certain precautions are necessary, especially when dealing with growths occupying the neighbourhood of serous cavities. In this connection Davaine's *Traité des Entozoaires* should be consulted, and also Hearn's clinical work, which, so far as hydatids of the thoracic cavity are concerned, is thoroughly exhaustive and reliable. We are entirely in accord with Hearn, who speaks as a true criterion of his estimate as to the value of drugs when he incidentally remarks

that the medical treatment of hydatids in no way affects the prognosis.

Prophylaxis.—The prophylactic treatment of hydatids deserves the most serious attention of those interested in the advance of State medicine. As all the circumstances favourable to the production of the echinococcus disorder are now well known, it clearly follows that the malady falls within the category of those endemics which admit of being either largely checked, or altogether stamped out. There is no need to recapitulate the etiology of the subject at any length, and the writer can only again insist upon the adoption of those measures which he has sought to enforce for many years past. He has recommended that boiling hot water should be thrown over the faeces of dogs, not only in kennels, but in all places where the excreta are exposed. To attempt to collect and burn the faeces would be too troublesome a process, and not so effective, since a large number of the invisible eggs scattered on the ground or flooring would inevitably escape. In this view, the late Dr. Leared's proposal that every dog should be efficiently purged with an anthelmintic and cathartic at certain intervals is worthy of attention. Dr. Leared further advised that the excreta should be buried, but the writer's plan of destruction of the germs by boiling water seems more effective and more easy of accomplishment. Professor Leuckart, in an elaborate but popularly written article, embodying a review of all the more important facts of helminthological study in relation to the public health (*Unsere Zeit*, 1862, s. 654), gives an admirable summary of the sanitary bearings of the subject in the following terms:—'In order to escape the dangers of infection, the dog must be watched, not only within the house, but whilst he is outside. He must not be allowed to visit either slaughter-houses or knackeries, and care must be taken that neither the offals nor hydatids found in such places are accessible to him. In this matter the sanitary inspector has many important duties to perform. The carelessness with which these offals have hitherto been disposed of, or even purposely given to the dog, must no longer be permitted, if the welfare of the digestive organs of mankind is to be considered. What good results may follow from the adoption of these precautions may be readily gathered from the consideration of the fact that, at present, almost the sixth part of all the inhabitants annually dying in Iceland fall victims to the echinococcus epidemic.' The Leipzig helminthologist next dwells upon the conditions already shown to be so eminently favourable to the production of the disorder, and concludes by remarking that 'cleanliness is one of the most important preservatives against infection.' Without doubt this is so; but, as a matter of fact, no amount of care in this respect will ensure immunity from hydatid disease. Occasionally, though happily very rarely, the most delicately nurtured persons, who have all their lifetime lived, as it were, in the lap of luxury, fall victims to the malady. One such case, that of a lady, was not very long ago brought under the writer's notice by an eminent practitioner, who tapped the abdominal tumour, at first suc-

carefully, but on a second occasion with a fatal result to the patient. The explanation of the occasional occurrence of hydatids in high life is not far to seek. The act of drinking a glass of water from some doubtfully good or unfiltered source, or, still more probably, the partaking of salad (derived from some market-garden source, and not properly cleansed before being sent to table), is quite sufficient to account for infection. A single invisible germ or echinococcus-ovum thus transferred to the stomach of the human host, is capable, after a lengthened interval, say of a year, of presenting itself as an hepatic tumour of considerable dimensions. What obtains thus infrequently amongst well-to-do persons in life, must necessarily happen more commonly to those whose occupations naturally bring them more directly in contact with the ordinary sources of infection. In a paper, 'On the comparative prevalence of different forms of entozoa infesting the dog' (*Linn. Soc. Journ.* 1867) the writer has called attention to the desirability of instituting special investigations in reference to the frequency of the occurrence of the hydatid tapeworm in the dog in England. By adopting, both at home and in our colonies, the admirable mode of procedure initiated by Krabbe in Iceland and Denmark, a large amount of valuable information, available for sanitary guidance, could not fail to be obtained. Hundreds of dogs are annually destroyed in this country, yet no public officer possessing a practical knowledge of the subject, has ever examined their carcasses with the view of ascertaining the prevalence or otherwise of parasites within them. The amount of good which has already been accomplished by private efforts (not unattended with personal sacrifices) in this direction is by no means inconsiderable. These efforts have led to the discovery of the causes of several destructive epidemics. In respect of the sexually mature echinococcus tapeworm, Dr Krabbe has shown that no less than 28 per cent. of Icelandic dogs are infested. His investigations have thus furnished us with a striking result, which, to the thoughtful and cultured sanitarian, readily explains the extraordinary prevalence of hydatids in that country. See ACCEPHALOCYSTS; BLANDER-WORMS; and ECHINOCOCCUS.

T. S. CORBOLD.

HYDATIDS, UTERINE See MOLA.

HYDRÆMIA (δῦρ, water, and αἷμα, the blood).—A watery condition of the blood. See ANÆMIA, and BLAUN, Morbid Conditions of.

HYDRAGOGUES (δῦρ, water, and ἄγω, I drive).—SYNON.: Fr. *Hydragogues*, Ger. *Wasserführende Mittel*.

DEFINITION.—Purgative medicines which cause a copious watery discharge.

ENUMERATION.—Hydragogue purgatives include: Bitartrate of Potash, Buckthorn, Colchicum, Colocynthis, Croton Oil, Elettarium, Gamboge, Hellebore, Jalap, Podophyllin, and Scammony.

ACTION.—It has been supposed by some writers that the action of the drugs included in the present class is due only to the increased peristaltic action which they produce. This, however, is not the case, as certainly some, if not all, of those just enumerated, induce

a free secretion of fluid by the intestinal mucous membrane, while at the same time they stimulate the peristaltic action of the bowel, and cause the evacuation of this watery fluid.

USES.—Hydragogues are chiefly employed for the removal of fluid from the body, in cases either of general anasarca or of dropsical effusion in serous cavities. They may be employed to assist the action of the kidneys when this is insufficient, and it has been observed not unfrequently, when the secretion of urine has previously been deficient, that it becomes greatly increased after a free discharge of fluid has taken place from the bowels, in consequence of the administration of a hydragogue cathartic. See PURGATIVES.

T. LAUDER BRANTON.

HYDRARGYRIASIS (*hydrargyrum*, mercury).—The state produced by the introduction of mercury into the system. See MERCURY, Poisoning by.

HYDRARTHROSIS (δῦρ, water, and ἄρθρον, a joint).—Effusion of a serous fluid into a joint. See JOINTS, Diseases of.

HYDROA (δῦρ, water).—A term used by Hippocrates, and expressive of a sweat-eruption. By the Latins the condition was named *madamum*, and in modern times it is called *milaria*. The term hydroa has also, with doubtful propriety, been applied to the larger vesicle of herpes; and more recently to herpes, or rather, pemphigus iris. ERASMUS WILSON.

HYDROADENTITIS (δῦρ, water, and ἄδης, a gland).—DESCRIPTION.—This affection was first described by Verneuil and Bazin as a minute phlegmon of the sweat-gland, resulting in a flat pustule, and met with chiefly in those situations where the sudatory glands are most largely developed, for example, in the axilla, on the areola of the nipple, and at the verge of the anus. Hydroadentitis occurs singly or in crops. It first becomes developed into a small tubercle; and, when pus forms, it breaks upon the surface, and the tubercle subsides. The disease has been attributed to irritation from friction, discharges, or absence of cleanliness, and is said to be favoured by an unhealthy constitution.

TREATMENT.—After the more obvious indications of improvement of the general health and removal of local irritants have been attended to, it has been recommended to paint the affected part with the liniment of iodine.

ERASMUS WILSON.

HYDROCARDIA (δῦρ, water, and καρδία, the heart).—An effusion of serous fluid into the pericardial sac. See PERICARDIUM, Diseases of.

HYDROCELE (δῦρ, water, and κύψα, a tumour).—SYNON.: Fr. *Hydrocèle*; Ger. *Wasserbruch*.

DEFINITION.—A swelling produced by a collection of fluid in connection with the testicle or spermatic cord.

DESCRIPTION.—The principal forms of hydrocele of the testicle are the vaginal, the congenital, and the encysted.

Vaginal Hydrocele.—DESCRIPTION.—This is a chronic dropsical effusion into the sac of the tunica vaginalis. The fluid is a pale-yellowish serum, which in old cases is often loaded with shu-

testicle. The quantity varies, but seldom exceeds twenty ounces. The writer has removed as many as forty-eight ounces. The testicle is usually situated at the back part and rather below the centre of the sac; but its position may be altered by adhesions; and, in cases of congenital inversion, the testicle is in front of the sac. In old hydroceles the sac is often greatly thickened by deposition of lymph on the tunica vaginalis, and its conversion into fibrous tissue, which is sometimes the seat of calcareous deposits. It is generally single, but often occurs on both sides. Vaginal hydrocele forms an oval or pyriform swelling, which fluctuates; has a smooth, even surface, and commences at the lower part of the scrotum, very gradually and without pain. When examined by transmitted light it is found to be translucent, except at the back part, where the testicle is situated. Owing to the tunica vaginalis remaining unobliterated for some distance along the cord, the swelling occasionally assumes an elongated form, and extends up towards the inguinal canal. A hydrocele sometimes varies in size, becoming larger and more tense during the day than when the patient first rises in the morning.

Ætiology.—Hydrocele is a common disease, especially in warm climates, and occurs at all periods of life, but is most common in middle age.

Diagnosis.—The circumstances—that the swelling commences below, that the spermatic cord can be detected above the tumour, that the testicle cannot be felt, and that the tumour receives no impulse on coughing, and does not vary in size on pressure—are signs distinguishing a hydrocele from an inguinal rupture. When the sac is much thickened, so as to obscure fluctuation, and prevent the passage of rays of light, the tumour may be mistaken for a hæmatocele, or disease of the testicle, and the diagnosis is difficult.

Treatment.—In *infants*, vaginal hydrocele usually disappears under the application of weak tincture of iodine. Acupuncture, causing the fluid to escape into the areolar tissue of the scrotum, is the only operation that is required.

In the *adult* external remedies are of no use. It is usual to resort at once to operative treatment, *palliative* or *radical*. The *palliative* operation consists in puncturing the tumour with a trochar, and evacuating the fluid accumulated in the tunica vaginalis. The hydrocele usually returns in the course of two or three months, and then the operation must be repeated, or the patient must undergo *radical* treatment. This may be effected by incision or excision of the sac; by the passage of a seton; or by injection of the sac with a stimulating fluid. The latter is the plan commonly resorted to; and the fluid almost invariably employed is the tincture of iodine. The only apparatus required, in addition to a medium-sized trochar, is a glass syringe. The writer generally injects about a drachm of strong tincture, which he leaves in the sac. It causes considerable pain, extending to the loins; but all suffering may be prevented by ether or chloroform inhalation. The iodine acts as a stimulant, stirring up mild inflammation, and causing a rapid return of swelling, which gradually subsides until the patient is cured. Compression with strapping helps the absorption. In

double hydrocele, injection may be performed on both sides at the same time. Injection rarely fails to cure the hydrocele. If it does not succeed, recourse can be had to the seton; or, in cases of thickened sac, to incision or excision.

Congenital Hydrocele.—In children, the original communication between the cavities of the peritoneum and of the tunica vaginalis sometimes fails to be obliterated; and fluid accumulated in the sac constitutes the variety termed congenital hydrocele. The communication is usually small in size.

Diagnosis.—Congenital hydrocele is easily distinguished from ordinary hydrocele by the absence of a defined boundary on the upper part of the tumour, by the impulse received on coughing, and by pressure causing the disappearance of the swelling, and rendering the testicle perceptible. It is distinguished from a reducible hernia by the fluctuation and transparency of the swelling, by the absence of gurgling accompanying its disappearance on pressure, and by the slow return of the swelling on the patient assuming the erect posture.

Treatment.—Congenital hydrocele is readily cured by the gentle pressure of a truss on the inguinal canal, so as to occasion obliteration of the neck of the sac, after which the fluid usually becomes absorbed.

Encysted Hydrocele.—In this form of hydrocele fluid is effused into an adventitious cyst distinct from the vaginal sac, developed in the areolar tissue beneath the visceral portion of the tunica vaginalis investing the head of the epididymis. As the cyst enlarges, the epididymis becomes flattened and displaced to one side, whilst the testicle is found either in front or at the bottom of the cyst. The fluid contained in the sac differs from that of vaginal hydrocele in being less in quantity, perfectly limpid and colourless, and nearly free from albumen. The fluid sometimes contains spermatozoa in great abundance, rendering it opaque and milky-looking. Their presence is owing to the rupture of one of the tubes of the epididymis, and the escape of semen into the sac of the hydrocele.

Diagnosis.—An encysted hydrocele is distinguished from vaginal hydrocele by the position of the testicle at the bottom of the tumour, and generally by the colourless character of the fluid evacuated.

Treatment.—When large in size, so as to be inconvenient, encysted hydrocele may be treated in the same way as vaginal hydrocele, and injection is attended with the same success.

Hydrocele of the Cord.—Hydrocele occurs in the spermatic cord in two forms—*diffused* and *encysted*.

The *diffused*, which is very rare, is simply an oedema of the areolar tissue of the cord.

Encysted hydrocele of the cord arises from a collection of fluid in the unobliterated fimbriar process of peritoneum, which is carried down in the natural transition of the testicle. It produces a small swelling in the cord, of an oval form, above and distinct from the testicle, more or less transparent, and quite movable. The swelling, when small, is of no importance; and it seldom requires treatment. See TESTES, Diseases of.

T. B. CURLING.

HYDROCEPHALOID DISEASE.—This term is one which has been applied to a set of symptoms, ill-defined in their mode of grouping, occasionally met with in delicate children soon after they have been weaned. The symptoms may in some cases have been due to reflex disturbance of the nervous system induced by improper food, they may appear as the sequence of some exhausting disease, such as a prolonged diarrhoea; or they may be concomitants of a pneumonia in its initial stages. In each of these, as well as in other allied conditions, there may be a febrile elevation of temperature, combined, in the first place, with undue irritability and extreme restlessness, whilst later on signs of mental sluggishness and stupor may supervene. Such symptoms are apt to be met with where, in addition to a depression of the vital powers, there is a reflex disturbance of brain-functions. The condition was specially described by Marshall Hall, by whom the above name was given. It may be well, therefore, to quote from his own description:—

‘This affection may be divided into two stages: the first that of irritability; the second that of torpor. In the former there appears to be a feeble attempt at reaction, in the latter the powers appear to be more prostrate. These two stages resemble in many of their symptoms the first and second stages of hydrocephalus respectively.

‘In the first stage the infant becomes irritable, restless, and feverish; the face flushed, the surface hot, and the pulse frequent; there is an undue sensitiveness of the nerves of feeling, and the little patient starts on being touched or on hearing any sudden noise, there are sighing and moaning during sleep, and screaming, the bowels are flatulent and loose, and the evacuations are mucous and disordered.

‘If through an erroneous notion as to the nature of this affection, nourishment and cordials be not given, or if the diarrhoea continue, either spontaneously or from the administration of medicine, the exhaustion which ensues is apt to lead to a very different train of symptoms. The countenance becomes pale, and the cheeks cool or cold, the eyelids are half-closed, the eyes are unfixed and unattracted by any object placed before them, the pupils unmoved on the approach of light; the breathing, from being quick, becomes irregular and affected by sighs, the voice becomes husky, and there is sometimes a husky, teasing cough, and eventually, if the strength of the little patient continue to decline, there is a crepitus or rattling in the breathing. The evacuations are usually green; the feet are apt to be cold.’

But in such groups of symptoms there is nothing distinctive; and the term hydrocephaloid, which is now seldom heard, might be discarded. Its use can scarcely be justified merely on the ground that the symptoms met with under such conditions are apt to be occasionally confounded with those which usher in the commencement of acute hydrocephalus. We do not diminish the difficulties—already sufficiently pronounced—besetting the early diagnosis of this latter affection, by endeavouring to group together under one name a set of symptoms which, on different occasions, have no other common bond than that they are apt to occur in delicate children, the

tone of whose nervous system has been lowered, and thereby rendered more irritable than natural. We should be really better without such a name, especially now that bleeding and lowering treatment are no longer in vogue for the amelioration of the grave organic affection with which the status in question may occasionally be confounded.

H. CHARLTON BASTIAN.

HYDROCEPHALUS, Acute (*Shop*, water, and *kephalē*, the head).—A synonym for Tubercular Meningitis. Tuberculosis *plus* a meningeal inflammation is the generating condition; and acute hydrocephalus is only the occasional, though very frequent, concomitant. See **MEINGITIS**, Tubercular.

HYDROCEPHALUS, Chronic.—**SYNON.** Water on the Brain, *Hydrops Capitis*; Fr. *Hydrocephale*, *Hydropneus du Cerveau*, Ger. *Der Wasserkopf*; *Hirnwassersucht*.

DEFINITION.—A gradual accumulation of serous fluid within the lateral and third ventricles of the brain, causing them to become more or less distended, and the head enlarged, occurring principally in infants or very young children; and leading to restlessness, irritability, or convulsions, followed by dulness, drowsiness, motor weakness or actual paralysis, together with failure of mind and of the special senses.

The essential condition in this malady is the intra-ventricular effusion. The cases in which the fluid has been found outside the brain and within the arachnoid sac are, in all probability, merely examples of the disease in which intra-ventricular effusion having previously been well-marked, the distended corpus callosum, or, it may be, the floor of the third ventricle has given way, and allowed the fluid to pass beneath the arachnoid. The so-called extra-ventricular form of the disease is, therefore, in the majority of cases, merely a secondary and altogether accidental condition.

As a sequence of a large arachnoid hæmorrhage, serous fluid may also be found within the arachnoid cavity; this, however, is a condition which has no real title to be mentioned under the head of chronic hydrocephalus, as some writers have done. And the same remark applies to those accumulations of serous fluid which take place beneath the arachnoid, as a sequence of wasting or atrophy of the cerebral hemispheres, one or both. The collection of fluid in such cases is to be regarded as a simple sequence of the atrophy, and is of itself unproductive of morbid symptoms.

ÆTIOLOGY.—Two principal groups of causes are appealed to as productive of chronic hydrocephalus. In certain cases the affection is believed to be *idiopathic*, due to an ‘essential dropy,’ occasioned by an inflammatory affection of the lining membrane of the ventricles. In other patients, however, this affection is distinctly *secondary* or *symptomatic*, and then may be caused by one or other of two principal sets of conditions. Thus (1) it is often occasioned, as writers of the last century pointed out, by the presence of *scrophulous* or other tumours upon the ‘straight sinus,’ producing mechanical congestion of the great veins of Galen as well as of their radicles on the walls of the lateral ventricles, and, as a conse-

quence, an increasing dropical condition of the ventricles themselves. (2) More rarely it seems to be produced or to remain as a sequence of an attack of acute hydrocephalus. This latter mode of origin is admitted by some authors, and denied by others. It is at least a possible mode of origin, although one which is difficult to be established with certainty. By far the largest percentage of cases probably belong to the first set of the 'symptomatic' category.

The disease is sometimes congenital, and may be so far developed during uterine life as to cause great difficulties in parturition—frequently necessitating the sacrifice of the life of the child. At other times the enlargement of the head begins to show itself soon after birth, or at some period before the end of the first or second year. Or it may reveal itself later still in childhood, much more rarely during adolescence; and more rarely still in adult life.

Congenital 'microcephalism' must not be confounded with hydrocephalus. It is true that in certain small-headed infants, having the cranium malformed and the sutures ossified, an excess of fluid may be found within the head; but then the fluid in these cases is situated outside the atrophied brain, and not within the ventricles. The two conditions are, in fact, totally opposite in nature.

ANATOMICAL CHARACTERS—Three different states, in regard to size of head, have been described as existing in this affection—(1) where the head is smaller than natural, (2) where the head is of natural size, and (3) where the head is more or less considerably enlarged.

Those of the first category ought not to be included at all. They are the cases of 'microcephalism' above referred to. Those of the second category could never be diagnosed with any degree of positiveness during life, and it may, indeed, be questioned whether such cases exist to any large extent, except as more or less transitory stages of instances of the disease pertaining to the third of the above categories.

Of course, in all the cases in which the head ultimately becomes enlarged from the presence of an excess of fluid within the lateral and third ventricles, there must have been a stage during which these ventricles were merely full of fluid, and during which pressure-symptoms were more or less marked even without the existence of actual enlargement of the head. Such symptoms alone, however, do not often form a sufficiently precise combination to enable us to do more than entertain a vague suspicion that we may have to do with a case of chronic hydrocephalus. We mostly need the objective sign of enlargement of the head, to enable us to arrive at a positive diagnosis of this disease; but as soon as this sign declares itself to a well-marked extent, there are few affections of the brain which can be diagnosed with more certainty than the one which we are now considering.

Even the cases in which the head is distinctly enlarged differ amongst themselves, since in some of them (a) both sutures and fontanelles are widely open; whilst in others (b) the sutures, and perhaps the fontanelles, are completely closed. It seems probable that the latter may represent conditions into which some of the

former pass, when the disease lapses into a chronic and stationary condition.

Owing to the separation of the cranial bones in young infants, this disease, when it occurs in them, soon becomes associated with an actual enlargement of the head, which increases rapidly. In consequence of the distending pressure from within, caused by the increasing size and fulness of the ventricles, the bones entering into the formation of the vault of the cranium become separated from one another, though the bones of the face remain unaltered. The frontal, parietal, the superior part of the occipital, and a small part of the squamous portion of the temporal bones become expanded and thinner than natural, at the same time that they are separated from one another—especially in the regions of the anterior and posterior fontanelles, and of the sagittal suture. In such regions, when the enlargement is extreme, a sense of fluctuation is often recognisable. The forehead becomes prominent and overhanging, whilst the eyeballs are depressed, and as the face remains unaltered or even becomes emaciated, it seems altogether unnaturally small, and thus contributes to produce a most characteristic appearance ('*facies hydrocephalica*'), which is often intensified by the old-looking, and more or less blank, expressionless, aspect of the face.

The cranial bones are often very thin, but occasionally they may be unusually thick throughout—even in young children.

The circumference of the head, even of a young child, may in hydrocephalus easily reach 24 to 30 inches or even more. Where the enlargement becomes extreme, the weight of the head is so great that it cannot be maintained in the upright position. It has to be supported by the hand or some artificial support; or else the child does not attempt to rise from the recumbent position. The size attained by the head in certain cases has been comparatively enormous; thus, in an altogether exceptional case, recorded by Cruikshank, it is said to have measured, in a child sixteen months old, no less than 52 inches in circumference, and the amount of fluid contained within the cranium was found to weigh as much as twenty-seven pounds.

The fluid is generally slightly albuminous; possesses some saline constituents; and has a specific gravity ranging from 1,006 to 1,014. Its composition agrees pretty closely with that of dropical fluids generally.

In the great majority of cases, as already stated, the fluid is contained within the more or less distended lateral and third ventricles of the brain. The upper and lateral parts of the cerebral hemispheres, as well as the corpus callosum, become thinned and distended, so as to resemble a mere bag, the walls of which are represented externally by pale unfolded and much flattened convoluted matter, and internally—next the fluid itself—by the lining membrane of the ventricles. This latter has become much thicker and tougher than natural; it may also be more or less granular on the surface, and often shows an increased number of distended vessels. These appearances are, however, not to be taken as an indication of the inflammatory origin of the malady, as some observers seem to suppose. They may be found, as the writer has seen, well-marked,

in cases where the effusion and distension has been the result of a mere mechanical congestion, produced by pressure upon the commencement of the straight sinus, owing to a tumour in the middle lobe of the cerebellum. On the other hand, some years ago the writer examined the head of a hydrocephalic child who died in University College Hospital, in whom the most careful search revealed nothing that could have produced mechanical congestion, and in which there was, moreover, no sign of anything like an inflammatory condition of the walls of the greatly distended lateral ventricles. To fall back upon the hypothesis of an 'essential dropsey' was felt to be far from satisfactory. Such a phrase cannot indeed be regarded as conveying any real explanation of the condition in question.

The shape of the ventricles and of the compressed ganglia about the base are, of course, greatly altered. The foramen of Munro may be half an inch or more in diameter. The optic and olfactory tracts and lobes are also often much altered by pressure.

The brain-substance may be even tougher than natural, because the long-continued mechanical congestion, which exists in so many cases, favours the overgrowth of the neuroglia, and, indeed, it would appear probable that in some instances the overgrowth of this mere connective substance is well-marked. For, notwithstanding all the pressure upon and distension of the brain-substance, this rarely shows signs of atrophy. It is rather the reverse. The mere brain alone of a hydrocephalic child, after the fluid has been evacuated, commonly weighs more than the brain of a healthy child of the same age. Thus in an instance that came under the writer's notice, the brain of a child five years of age weighed rather more than 52 oz.

In those cases in which during life the fluid has escaped from the ventricles through a rupture in the corpus callosum, the brain has been found more or less flattened and collapsed in the lower part of the enlarged cranium, whilst the escaped fluid occupies the arachnoid cavity above it.

SYMPTOMS.—Chronic hydrocephalus begins to manifest itself in various ways, and also, as above stated, at various ages. The great bulk of the cases are either congenital, or commence before the fifth month. But in certain rare instances, the head may begin to enlarge long after the union of the sutures, in early adult life, or even beyond middle age.

As to modes of commencement, at least four, pretty distinct from one another, may be encountered. (1) The disease may be ushered in by a period of fretfulness and irritability, with or without the occurrence of convulsions and strabismus, before any enlargement of the head is detected. Or (2) slow enlargement of the head may be noticed as the first event. In some cases, this enlargement not only sets in, but may continue for months, till notable increase in size has taken place, and yet the child may exhibit no morbid symptom whatever. The writer has seen a well-marked instance of this in a child whose head had been enlarging for eighteen months (the process beginning when it was a year old), and in whom, though the head was twenty-four inches in circumference, no other morbid

signs or symptoms presented themselves. (3) Chronic hydrocephalus may supervene in a child after a fall, through the intermediation of cerebellar disease. The writer had under his care a little girl four years old, who, after falling from a table and striking the occiput severely, suffered for from twelve to eighteen months from symptoms indicative of cerebellar disease, after which the head began to enlarge, and hydrocephalus became the apparently dominant condition. Complete blindness ensued, then convulsions set in, and in the midst of one of these the patient died. A tumour of the middle lobe of the cerebellum was found, *plus* all the signs of a well-marked hydrocephalus. (4) The disease may occur as a sequence of an attack resembling acute hydrocephalus (tubercular meningitis); that is to say, a child appears to suffer for a time from what is regarded as tubercular meningitis; the symptoms then undergo some mitigation; they become more or less chronic, and ultimately the head begins to enlarge, as it does in chronic hydrocephalus. There is some doubt about the real nature of the starting-point in this mode of origin. The initial symptoms may not in reality have been those of tubercular meningitis. The chronic disease and its symptoms may occasionally be initiated in an acute manner.

It may be easily imagined that the subsequent course of the symptoms in persons suffering from chronic hydrocephalus, beginning in these various ways, may also be subject to great variations.

As the head enlarges, or as the pressure within increases, sensations of weight or pain may be experienced. The child may show increased fretfulness and irritability, or its manner may become more dull and heavy than natural. At other times there is no noticeable change in these respects.

In the 'symptomatic' forms associated with tumours, there is apt to be vomiting of a very obstinate and paroxysmal character, together with continuous pain marked by exacerbations. Convulsions, either unilateral or general, may also occur, as well as paralysis of one or other of the ocular muscles. In such cases, too, in comparatively early stages, ophthalmoscopic examination will frequently reveal optic neuritis, which has a tendency to go on to white atrophy, with the production of more or less complete blindness.

In later stages of the disease mental action becomes increasingly impaired, there is loss of memory, dulness, and a great tendency to sleep during the day. There may be marked weakness or actual paralysis of limbs. Children affected to this extent often keep to the recumbent position having at last no power of sitting up, or even of raising their head from the pillow. The appetite sometimes remains good; at other times it becomes much impaired, and a gradual emaciation ensues. Blindness, more rarely deafness, loss of smell, and impairment of other senses tend gradually to reveal themselves after a time.

COMPLICATIONS.—In all cases where the hydrocephalus is itself symptomatic of some primary intra-cranial disease, interfering with the proper return of blood from the ventricles and central portions of the brain, the symptoms resulting from this latter state of things are necessarily

complicated with others immediately produced by the original morbid condition. Hence the very great variations encountered in the grouping of symptoms in different cases.

DIAGNOSIS.—Some remarks have already been incidentally made upon this subject under the head of *Anatomical Characters*.

Where the head becomes distinctly enlarged, with widely separated sutures and open fontanelles, there can be scarcely any room for doubt about the diagnosis. But before the head is distinctly enlarged, the diagnosis of chronic hydrocephalus with any degree of certainty is impossible. In many cases also where the head is only slightly enlarged, and the sutures are not opened, it may be very difficult, for a time, to pronounce an opinion as to whether or not an infant or young child is hydrocephalic. Natural variations in the size of the head are considerable; and it may also be enlarged from rickets, or from that very rare condition known as 'hypertrophy of the brain.' Even great thickenings of the bones of the head have occasionally given rise to uncertainties in regard to diagnosis. But in all these cases, in order to enable the practitioner to arrive at a trustworthy opinion, the particular form of the head has to be considered, together with the sum-total of the various symptoms which may have preceded or accompanied its increase.

Whether in any particular case we have to do with an instance of 'idiopathic' or of 'symptomatic' hydrocephalus, often cannot be settled; but in others it can be decided by reason of the existence of a set of symptoms distinctly pointing to the presence of an intracranial new growth.

PROGNOSIS.—Hydrocephalus often proves fatal in the course of a few months, or it may be less rapid, entailing death only after a year or two. Its progress is variable, however. Remissions and stationary conditions are apt to occur, chequered by periods in which there are distinct exacerbations of all the symptoms.

Occasionally one of these stationary conditions becomes prolonged, and the individual may live for years. Some hydrocephalic subjects have subsequently lived on to the age of twenty, thirty, or even forty years. In a few exceptional cases a cure seems to have been effected, either naturally or under the influence of remedial agencies.

Death may take place in convulsions; from slow exhaustion with emaciation, or from intercurrent pneumonia or some other acute disease.

TREATMENT.—Very little, unfortunately, can be done, in the majority of cases, to produce decided or lasting improvement. This is especially so in those instances—only too numerous—in which the hydrocephalus is due to some scrofulous or other tumour interfering with the return of blood from the ventricles.

Blistering of the scalp, with mercurial inunctions, formerly much lauded, may do a great deal more harm than good; and the same may be said in reference to pressure of the enlarged head by strapping or bandages. This latter is a barbarously coarse method of treatment, which has happily fallen into disuse. Blistering may do good in some cases, but it should be cautiously had recourse to.

The general health of the child must be maintained as much as possible, by the aid, if necessary, of tonics and cod-liver oil. Purgation and diuretics may also be had recourse to. Iodide of potassium may be given internally in gradually increasing doses, as even young children bear this remedy well. Bromide of potassium will also help, perhaps, to mitigate vomiting and convulsions, when these are urgent symptoms.

It may be worth while in suitable cases to try the effect of greatly diminishing the amount of fluids taken, so as to reduce the fullness of the vascular system. The writer has had reason to believe that this method is well worthy of being attempted, where other means have failed, and where there is any chance of being able to carry it out.

Puncture of the head has been much lauded, and practised by many, but with an amount of failure and fatality that has caused the method almost to have fallen into disuse. If in any given case we could be reasonably certain that the hydrocephalus belonged to the 'idiopathic' variety (if there really are such cases), the method might be had recourse to, with much more chance of success than if it were occasioned by some mechanical pressure, which persists and prevents the return of blood from the central parts of the brain. Puncture of the head can scarcely be compared with puncture of the chest, because (even apart from the greater risks attaching to the former operation), a puncture of the chest in a case of pleurisy has a fair chance of being actually curative, whilst puncture of the head in hydrocephalus, in the majority of cases and for the reason above indicated, could only be palliative. Still the cases of this disease are so grave that where the sutures are opened, where the patient's condition is rapidly getting worse, and death seems otherwise inevitable, the question of performing the operation, at least once, ought to be entertained as a barely possible means of affording relief.

H. CHAMBERLAIN HASTIAN.

HYDROMETRA (ὕδωρ, water, and μέτρα, the womb).—Dropsy of the womb. See WOMB, Diseases of.

HYDRONEPHROSIS (ὕδωρ, water, and νεφρός, the kidney) ΣΙΛΑΝ. Dropsy of the kidney; Fr *Hydronephrose*, Ger. *Hydronephrose*.

DEFINITION.—A chronic disease of the kidney, caused by obstruction of the ureter, consisting in dilatation of the pelvis, and commonly of the ureter, with more or less extensive atrophy of the substance of the organ; usually affecting one kidney, sometimes both; characterized clinically by the presence of a soft fluctuating tumour in the renal region, but most distinctively by sudden discharge of urine with collapse of the tumour, and resulting, if not relieved, in complete destruction of the kidney.

ÆTIOLOGY.—Among the most common causes of hydronephrosis are obstruction of the ureter at its lowest part, in consequence of pressure by new formations, particularly carcinoma of the uterus; the impaction of calculi of various kinds; and tumour of the ovary. More rarely it is induced by new formations in the bladder, stricture of the urethra; the pressure of the

pregnant, prolapsed, or retroflexed uterus; and exceptionally it is met with without apparent cause. In such cases it is to be referred to some contraction, due to inflammation or other cause, which has disappeared. The condition is also sometimes congenital, being due to malformations, such as impermeable ureter, or valve-like obstruction to the passage of urine downwards. From whatever cause the obstruction spring, accumulation of urine takes place behind it, leading to gradual distension of the organ. See URETERS, Diseases of.

ANATOMICAL CHARACTERS.—In the earlier stage of hydronephrosis there is simple dilatation of the pelvis of the kidney. As the disease advances, the dilatation increases, the organ becomes more and more distended, and the ureter often becomes so dilated or elongated as to present the appearance of a bluish-white tube, as large as or even larger than the inferior vena cava. Coincidentally with this distension the substance of the kidney atrophies. At first the apices of the cones become flattened and wasted, but gradually the renal substance becomes more involved, until at length, in old-standing cases, scarcely any trace of it remains, and the kidney is represented by a large lobulated bag, whose fibrous walls are distended by clear fluid. Commonly one kidney only is affected, especially when extreme dilatation exists, but in some instances both kidneys are involved. There is a case on record where the whole abdominal cavity was occupied by an enormous tumour, containing sixty pounds of fluid.

SYMPTOMS.—In the slighter cases of hydronephrosis there are no symptoms of such a kind as to attract attention. This condition is often an unimportant complication of other serious diseases. In the more severe cases there are no constitutional symptoms, but the local changes are well-marked. There is a tumour situated in the lumbar region, extending upwards, downwards into adjacent regions, or forwards towards the anterior abdominal wall. The colon is usually in front of the tumour, and always displaced and compressed, so that constipation frequently co-exists with hydronephrosis. The mass is often lobulated, always undulating in character, and frequently fluctuation may be detected. The most conclusive evidence of the condition is afforded by the discharge of a large quantity of urine, generally of low specific gravity, and often containing mucus coincidently with the disappearance or diminution of the tumour. It sometimes happens that the obstruction is permanently removed, and dilatation alone remains as evidence of the old obstruction. Hydronephrosis, when double, sooner or later proves fatal by suppression of urine or uræmia. When only existing on one side, it has proved fatal by pressure upon neighbouring parts, by the supervention of impaction of stone in the kidney of the opposite side; or from other causes.

DIAGNOSIS.—The distinction of hydronephrosis from ascites may be sometimes difficult when the disease affects both sides. The diagnosis is partly to be made by observing the effects of change of posture, hydronephrosis being much less influenced thereby than ascites. The history and mode of origin of the affection also afford indi-

cations. From hydatids of the kidney it is sometimes impossible to discriminate hydronephrosis, but the history of the case and the characters of the urine often afford a clue. If there be tumour on both sides, it is extremely unlikely to be hydatid. From ovarian tumour the diagnosis is to be made by the history of the case; the position of the mass; its relations to the colon; and by vaginal and rectal examination. From perinephritic abscess hydronephrosis is distinguished by its being less hard, and by the absence of pain and fever.

PROGNOSIS.—The prognosis is always serious; but if one of the kidneys be sound it becomes enlarged, and does double work, and so long as this condition continues, the patient may suffer little inconvenience.

TREATMENT.—Careful manipulation of the tumour is often useful in extreme conditions; and tapping with the aspirator may be employed.

T. GRAINGER STUART.

HYDROPATHY (*Hydro*, water, and *πάθος*, a disease).—A synonym for hydrotherapeutics. See HYDROTHERAPEUTICS.

HYDROPERICARDIUM (*Hydro*, water; and *pericardium*, the pericardium).—An accumulation of serum in the pericardium, either dropsical or inflammatory. See PERICARDIUM, Diseases of.

HYDROPHOBIA (*Hydro*, water, and *φῶβος*, fear).—**SYNON.**: Rabies; Dog-madness; *Fr. Lyssa*; *la Rage*; *Ger. Hundswuth*; *Wasserwuth*.

DEFINITION.—An acute disease, produced by the inoculation of a specific animal poison; manifesting itself by symptoms due to disturbance of the central nervous system; and almost invariably proving fatal.

ÆTIOLOGY.—Never spontaneous in man, the sole cause of hydrophobia is inoculation with the poison of a rabid animal, almost invariably with the saliva, the inoculation being commonly effected by a bite. In about nine-tenths of the cases, the disease is contracted from dogs; in most of the remainder from cats; in very few cases from foxes or wolves. It has been acquired from a wound received during the dissection of a rabid animal. It is probable, although not certain, that inoculation with the blood of a rabid animal will produce the disease. The poison is not known to be present in any other secretion than the saliva. Commencing decomposition is said to destroy its activity, but it is probable that the dried saliva will retain its virulence for a considerable period.

Inoculation takes place more certainly by a bite on an uncovered part of the body, as on the hands and face, than by a bite inflicted through the clothes. It may occur without a bite, as by a lick upon an abrasion. It has followed the scratch of a cat, probably by the animal's saliva being thus inoculated. A healthy dog has communicated the disease by a bite given immediately after it had been fighting with a rabid animal, the saliva of which, no doubt, was hanging about its jaws. The disease has resulted from the teeth being used to loosen a knot upon a rope with which a rabid dog had been tied.

It has been asserted that the disease may

arise from the bite of a healthy dog, but this is improbable. Cases are on record, however, in which the disease has followed the bite of a dog, which did not at the time, or for several weeks afterwards, present the recognised symptoms of the disorder. It seems possible that in rare cases rabies may affect a dog as a mild and insignificant malady.

When no preventive measures are adopted, at least half, perhaps two-thirds, of persons bitten escape. The immunity may be due partly to the bites being inflicted through clothes, partly to individual insusceptibility, which has been found to exist in animals as well as in man. When preventive measures are adopted as soon as possible, the proportion of those who escape is much greater.

More males than females suffer, the proportion being three to one. So, too, in dogs. The largest number of cases occur in the middle-period of life, doubtless from greater exposure to the cause. Children, however, often suffer, being helpless and bitten about the face. Most cases are contracted from straying or pot dogs.

The period of incubation is longer than that of any other acute specific disease, and is singularly variable. It is rarely less than a month, the shortest on record having been about twelve days. The average period is six or seven weeks. In about half the cases it is between one and three months. In some cases it is longer, reaching six, nine, or twelve months. Cases have been recorded in which two, three, five, and even ten years intervened. Most authorities believe that such cases were either not true hydrophobia, or were due to a second unknown infection. If we admit, however, as we must do, that twelve or eighteen months may elapse, we can scarcely deny the possibility, or even probability, of longer periods. It is as hard to explain an incubation period of one year as of five years.

ANATOMICAL CHARACTERS.—General fluidity of the blood, such as is met with after death from acute septic diseases, redness of the throat and pharynx, and occasionally of the salivary glands, together with, in some cases, evidence of congestion of the brain and spinal cord, constitute the chief morbid appearances visible to the naked eye. The microscope has shown that there is evidence of inflammation (congestion and leucocytic infiltration) in the salivary glands (Coats); and that minute changes in the nerve-centres are almost constantly to be found (Clifford Allbutt, Hammond, Benedikt, Coats, and the writer). Of eight cases examined by the writer, the minute changes in seven were distinct, and in character and position so far characteristic that, given the fact of an acute disease, a *post-mortem* diagnosis might, in the vast majority of cases, be made with certainty by the microscope. The essential change consists in the accumulation of leucocytes around the vessels, and their infiltration into the adjacent tissue; this change having a special distribution, being either confined to, or most intense in, the region of the medulla which is contiguous to the lower part of the fourth ventricle, that is, the neighbourhood of the respiratory centre. Here we have also the convulsive centre, and the centre for deglutition. The change is most intense

in the hypoglossal, glosso-pharyngeal, and vagal nuclei and their neighbourhood. There is little or no change in the upper part of the medulla, corpora quadrigemina, cerebellum, or basal ganglia. In the convolutions a similar but slighter alteration is present in some cases. It may occur throughout the grey matter of the cord, but is here usually slight, and often absent. In the most affected regions, tracks of *ante-mortem* clots and even of inflammation of the walls of the minute vessels may be found in some cases. Perivascular areas of disintegration are common; but such frequently occur apart from hydrophobia or any other disease. Minute extravasations are common, partly mechanical. The only change in the nerve-elements themselves consists in a granular degeneration of the ganglion-cells of the regions chiefly diseased. In the dog the changes are quite similar in characters and distribution.

SYMPTOMS.—During the period of incubation of hydrophobia there are commonly no symptoms. Vesicles under the tongue were formerly described, but their occurrence has not been confirmed. Occasionally pain and discomfort have been felt in the seat of the wound, explicable, in part, by the attention directed to it. Mental depression has been noted, also probably due to anxiety regarding the possible consequences of the bite.

The onset of the acute symptoms is commonly attended by no local disturbance, sometimes by pain, rarely by actual inflammation, in the wound. The first evidence of the impending disorder is usually malaise, mental depression, disturbed sleep, and some discomfort about the throat, with a difficulty in swallowing, especially liquids. The attempt occasions some spasm in the throat, which soon, if not at first, involves the muscles of respiration, causing a short, quick inspiration, a catch in the breath, resembling that due to an effusion of cold water. In a few hours this increases to a strong inspiratory effort, in which the extraordinary muscles of respiration take more part than the diaphragm, the shoulders are raised, the angles of the mouth are drawn outwards. The saliva, which is abundant and viscid, cannot be swallowed. It hangs about the mouth, and the patient is annoyed by his efforts to get rid of it. As the intensity of the spasm increases, so does the readiness with which it is excited. The mere contact of water with the lips, or cutaneous impressions, as a draught of air, will bring on a pueroyism. The distress it occasions leads to a mental state which increases the readiness with which the spasm is produced. The mere sight of water, or the sound of dropping water, will cause it (hence the name), and even analogous visual impressions, as a sudden light or the reflection from a looking-glass. Thus the respiratory spasm excited by swallowing liquids, which is, as it were, the key-note of the disease, extends on the one hand to widely-spread muscular spasm, and on the other to mental disturbance. In each of these directions the symptoms develop. The spasm, from being limited to the muscles of respiration, may become general and convulsive (tetanoid or co-ordinated) in character, still excited by the same causes. The mental distress passes into disturbance, in which the balance of reason is

lost, continuously or during the paroxysms. In the frenzy, the horror of the distress is transferred to the attendants by whom any discomfort may have been occasioned, and during the paroxysms the patient may attempt to bite them, and even others. Consciousness may so far remain that in the intervals he may beg those whom he regards to keep away. The saliva is ejected with force, and the patient hawks it up with a noise 'like a dog.' The sight of a dog has been known greatly to intensify the disturbance; and this, strangely enough, in cases in which the sufferer had no suspicion of the nature of his affection. The delirium may, in some cases, be continuous and violent. As the mental disturbance increases, the respiratory spasm and convulsion may lessen, or the latter may persist to the end.

Vomiting is common, and is often an early symptom, a greenish-brown liquid being ejected. Priapism or nymphomania occasionally occurs. The temperature is usually raised two or three degrees. Albumen is often present in the urine; and sometimes sugar.

DURATION AND TERMINATIONS.—The duration of hydrophobia is usually from one to four days; sometimes it lasts six, eight, or ten days. In the rare cases which have recovered, the duration of the acute affection has been from four to ten days, although slight spasmodic symptoms have lasted for a longer time, as does the spasm of whooping cough.

The common cause of death is exhaustion from the attacks of fury and convulsion, often aided by manifest cardiac failure, which may occur early, and be out of proportion to the general asthenia. Sometimes the patient has died asphyxiated in a paroxysm of respiratory spasm; partly, perhaps, from spasm of the glottis.

VALENTINE.—The relative degree of the above-described symptoms varies in different cases. The mental disturbance, or general muscular spasm, may, respectively, predominate over the respiratory throat-spasm, even in the early stages, and may impress a special character on the attack, so that it resembles in the one case a primary mental affection in the other general convulsive affection, as tetanus.

PATHOLOGY.—We know nothing of the nature of the poison of rabies. It has been thought that it is not at once generalised, but develops in the wound, and subsequently affects the system. The symptoms indicate a primary action on the nerve-centres, especially on the respiratory region of the medulla, spreading more widely, in its ultimate action, in the medulla and to the brain and cord. The vascular changes, from their variability and occasional absence, are probably secondary effects of the disturbed action of the nerve-centre, produced by the poison carried by the blood.

The first effect of the poison is probably to lessen the 'resistance' of the medullary centres. Their action becomes spasmodic; is excited with undue readiness, especially by reflex influences; and spreads too widely. The secondary vascular changes may have their own effects. They are, as in other functional diseases, somewhat random in distribution within the affected area. By the infiltration of leucocytes, the tissue may be broken

up, and what are practically minute points of suppuration may result. If the part damaged is important, grave consequences may ensue. The nucleus of the pneumogastric is often so damaged, and thus we can understand the occurrence of cardiac failure. The changes in the convolutions and the spinal cord are probably proportioned to the mental or tetanoid symptoms respectively. The mental excitement no doubt acts upon and increases the irritability of the medulla (Putnam). Conversely, the disturbance of the latter may help to determine the direction of the mental disturbance due to the poison.

DIAGNOSIS.—The symptom of greatest diagnostic value is the respiratory spasm excited by attempts to swallow, increasing until it resembles a convulsive action, and accompanied after a time by mental disturbance. In certain diseases of the throat and chest especially oesophagitis and pericarditis, a reflex throat-spasm may occur, but in such cases there are commonly pain or other obtrusive signs of the local affection. When the mental disturbance occurs early, the affection may be confounded with acute mania; the association with slight respiratory spasm is still the most important diagnostic indication. In cases (if such occur) in which this symptom is absent, the diagnosis is a matter of great difficulty, and can only be made by the history of the antecedent bite, the rapid course of the disease, and its association with other convulsive phenomena and with salivation. From tetanus, hydrophobia is distinguished by the late period after the bite at which the symptoms develop, the absence of trismus and of continuous spasm; and the presence of paroxysmal respiratory spasm, of aversion to liquids, and of mental disturbance. Too much weight must not be given to the general character of the convulsive symptoms, if other signs of the disease are present, since there is probably a tetanoid form of hydrophobia, in which general spasms occur early, but they intermit, and are excited by attempts at deglutition, and there is no trismus. Organic brain-diseases accompanied by delirium and convulsions, occurring after a bite, have been mistaken for hydrophobia, as in a case in which the nature of the disease was only discovered when, after exhumation, meningeal hæmorrhage was found. Here also the respiratory spasm is absent.

More mental excitement, directed to the disease, may determine symptoms of dysphagia somewhat resembling the genuine disease—'spurious hydrophobia' as it has been termed. After a period of anxiety regarding the consequences of a bite, spasm in the throat is felt in swallowing. The patient's fears are intensified, the symptom increases, and even the medical attendant may be deceived. The spasm, however, is not of the respiratory character of genuine hydrophobia. Recovery commonly ensues on the mind being tranquillised, or by the application of some remedy in which the patient has confidence. It must be remembered that in some cases of genuine hydrophobia the influence of the patient's mental state has been very clearly traceable even in the early symptoms.

The distinction of genuine from spurious hydrophobia is often rendered difficult by the

fact that the latter usually follows suspicious bites, and that the former may be distinctly intensified by the patient's nervous fears. The untypical character of the spasm in the spurious disease (mere dysphagia); the fact that an effort removes this difficulty, and that once overcome it does not return, the stationary condition; the absence of mental symptoms beyond anxiety; and the disappearance of the symptoms when this is removed, are the important guides.

Prognosis.—Hydrophobia is practically fatal, but not certainly so; and the patient personally should unquestionably receive the benefit of the doubt. Cases differ in the intensity and rapidity of their course; and the less rapidly the symptoms are evolved, the greater is the hope, slight though it still is, that an exception to the common fatality may be obtained. The prognosis is better the longer the spasm remains limited; it is worse if there are general convulsions, mental disturbance, and signs of exhaustion or of disproportionate heart-failure.

Treatment.—Adequate measures against the spread of rabies would undoubtedly lessen, perhaps entirely prevent, the occurrence of hydrophobia in man; but the discussion of these is beyond the scope of this article (see RABIES). When a person has been bitten by a suspicious or doubtful animal, the circulation in the part should, if possible, be at once arrested by a tight ligature above the place; the wound should be washed; and then it should be allowed to bleed freely. It may probably be sucked with impunity if the mouth is rinsed with water, or better still with vinegar and water, after each act, and if there are no abrasions in the mucous membrane. The act has been supposed to be dangerous, but all experience is opposed to this. Poisons have to remain for some minutes in contact with a mucous membrane before they are absorbed, and during the act of sucking there is a flow from the mucous membrane into the mouth, which must be opposed to absorption. As soon as possible the wound should be cauterised. Of chemical caustics, nitrate of silver, freely applied at once, is probably effectual. If any time have elapsed, nitric acid or liquid carbolic acid is preferable. The actual cautery, applied deeply and freely, is an efficient and ready means. If practicable, free excision of the bite is wise, and should not be neglected, even though the cautery has before been used, if there is any doubt as to the thoroughness of the application.

The methods adopted for the treatment of the developed disease have been numerous. All so-called 'specifics' have been proved to be useless. An attempt has been made to eliminate the poison by administering large doses of mercury, and by diaphoresis. The two have been combined in the mercurial vapour bath. Two or three cases are on record in which this method has been successful; many in which it has been powerless. Of late it has been but little tried.

Attention has been lately directed to curara as a remedy for hydrophobia. First recommended half a century ago by an Englishman (Sewell), it was tried in small doses and failed. Niemeyer suggested larger doses, and in a case by Offenbarg it was apparently successful; and since then another case, in America, has recovered

under its use. In many cases it has failed—in all cases in this country up to the present time. It is recommended that it should be used in injections of from $\frac{1}{4}$ to $\frac{1}{2}$ of a grain, repeated every quarter or half an hour, until the severity of the paroxysms is lessened. This point may not, however, be reached until general muscular paralysis is imminent or produced, and then artificial respiration may be necessary until the effect has passed away. As often as this is the case, and the spasms recur another injection must be given. In hydrophobia there is remarkable tolerance of the drug, poisonous doses (one grain repeated) of active curara having in one case been without any effect (Curtis). This is, perhaps, a hopeful fact, as it indicates that curara has an action to which the changes in the central nervous system are opposed.

Sedatives have been the remedies commonly employed, and of these the best are chloral and morphia. One case (probably genuine), in which morphia and chloral were used, recovered (Nicholls), and one in which chloral was employed lived for ten days (Sansom). The effect of the two on the respiratory centre in animals suggests their joint use. The morphia should be given by hypodermic, the chloral by rectal injection. Chloroform is useful in moderating the paroxysms, but appears somewhat inferior to chloral. Other sedatives—Indian hemp, &c.—have appeared of inferior value.

Cold affusions to the cervical spine and head were used in India in two cases which recovered the throat and spine being blistered with nitrate of silver, and chloroform administered. Ice to the spine has been tried without effect. Tracheotomy was recommended by Marshall Hall in one case. Death from laryngeal spasm, is, however, too rare to justify the measure.

In all cases tranquillity is of the greatest importance. Every excitant of spasm should be avoided; the patient being kept in a dim still room, and friends as much as possible excluded. Next in importance is nourishment, which should be given by the rectum, if spasm is excited by the attempt to swallow. Restraint, which may be necessary, should be as little as possible, but it should be effectual.

The saliva of persons suffering from hydrophobia has been proved to be capable of communicating the disease to animals. Hence the attendants should be cautioned to have no uncovered abrasion on the hands, and to wash from the eyes or face any saliva which may have been spit on them, and if they are bitten by the patient, the wound should be treated as if it had been inflicted by a rabid animal. These precautions remove all danger; and any anxiety the subjects may feel may be relieved by the assurance, that of the thousands of persons who have attended on patients with hydrophobia, no authentic instance has ever been recorded in which the disease was contracted either by attendance during life, or inspection after death. W. R. GOWERS.

HYDROPS (*Œdema*, water).—A synonym for dropsy. See DROPSY.

• **HYDRORHACHIS** (*Œdema*, water, and *ráxis*, the spine).—A collection of fluid in the spinal canal. The term is commonly used as a synonym for *spina bifida*. See SPINA BIFIDA.

HYDROTHERAPEUTICS (Böhm, water, and *Seperatim*, I treat).--SYNON.: Water-cure; Hydropathy; Fr *Hydrothérapiques*, Ger. *Wasserheilkunde*.

It would be out of place were we to enter here into a description of the sources and the composition of the numerous varieties of water used for hygienic and dietetic purposes; but we may refer to Dr. Parkes' instructive *Manual of Practical Hygiene*. We intend to divide this article into (1) a short sketch of the history of the water-cure or hydrotherapeutics, (2) *addition* on the internal use of water, and on the more common hydrotherapeutic procedures; and (3), a consideration of the morbid conditions suitable for hydrotherapeutic treatment.

History of the Water-cure.—Although the old Greek and Roman physicians occasionally employed water internally and externally in the treatment of disease, the systematic water-treatment seems to have gained ground for the first time in the 15th and in the beginning of the 16th century in Italy and France, and again after a period of oblivion in the 17th century, especially in England (Floyer, T. Smith), and in the beginning of the 18th century in Germany (F. Hoffmann). The next important scientific application we owe to J. G. and J. S. Hahn, who, towards the middle of the 18th century, treated febrile diseases with cold sponging, and were so convinced of the beneficial result, that one of them when attacked with typhoid fever subjected himself to this treatment. It fell, however, again into neglect, until towards the latter part of the 18th century, when Wm. Wright, James Currie, W. Jackson, and others resurrected the cold water treatment in fevers, and strengthened their reasoning by thermometric observations. In spite of the results obtained, not only in England, but also in Germany, amongst others by Reuss, Frohlich, Brandis, and Horn, the method was again falling into disuse, when, soon after 1820, a small farmer, Vincent Priessnitz, of Graefenberg, in Silesia, began to treat every kind of ailment, chronic as well as acute, with various hydrotherapeutic procedures, and added to the external applications the abundant internal use of water, combined with active exercise, and a very simple diet, prohibiting at the same time all alcoholic beverages, and also tea and coffee. Priessnitz gradually made considerable changes in his method of treatment. For the original packing during several hours in dry woollen blankets covered with feather-beds, and followed by cold infusions, he substituted packing in wet linen sheets during several hours, followed by a full bath or a douche, and at a still later period, he frequently employed cold wet packing of only 15 or 20 minutes' duration, repeated several times on the same day; he introduced also the method of rubbing the whole body with a cold wet or dripping sheet instead of the full bath, and made extensive use of partial baths, as hip or sitz baths, baths for the hands, the arms, the feet, wet abdominal belts, and wet compresses over different parts of the body. Priessnitz seemed to search for a universal method applicable to all cases. One of the guiding ideas was that disease of the most different nature was caused by an acrid humour in the blood, and that the skin was the organ through which this humour was to be removed.

Though the success of such treatment, combined with active exercise in a healthy mountainous country, and simple diet, was considerable in many cases, the indiscriminate, too energetic, and promiscuous use often led to unfavourable results, and the system was beginning to be regarded as a species of quackery, when, about thirty years ago, some establishments were placed under the superintendence of regularly educated physicians, who studied the physiological effects of the different forms of bathing, and modified them with regard to duration, temperature, &c., according to the requirements of individual cases, combining pharmaceutical remedies with hydrotherapeutic procedures when required. Thus a more or less modified water-cure has at last become a branch of rational medicine, at least in France and Germany; and a new impulse has been given to it lately, by the employment of various forms of baths in the treatment of fevers. In this country there is as yet, very little systematised relation between the special hydrotherapeutic and the general medical treatment; and the experience gained at hydrotherapeutic establishments is not communicated and discussed in our medical societies, and scarcely even in the general medical journals. This is much to be regretted, for there can be no doubt that hydrotherapeutic measures might be more widely introduced with great advantage into our hospitals, as well as into our private practice; but this is not likely to be the case so long as the medical profession has not fuller opportunities for studying the effects of water treatment. The fault may lie to some degree in the nature of most of the establishments for the water-cure, but this might be remedied if more establishments were to be erected under the guidance of superior members of the profession—establishments where the usual medical treatment would in suitable cases go hand in hand with hydrotherapeutic management.

Internal Therapeutic Use of Water, and the more Common External Hydrotherapeutic Procedures.—The dietetic necessity of water is well known; life cannot exist without it, all our tissues contain an indispensable proportion of water; we constantly lose a large amount by respiration, and by all excretions; all the internal functions of tissue-change are dependent on a certain quantity of water, this want is supplied by the solid and fluid food which we take, water included, while temporary excess of supply leads to increased discharge by the excretions, and temporary deficiency to a diminution of the water of the excretions. An increased ingestion of water further leads, for a time at least, to an increased removal of the products of retrogressive tissue-change; the tissues and the blood itself are, so to speak, washed out by it; and, as the consequence of the increased removal of the used-up material, the body is enabled to take in a larger amount of new substance, and hence we observe not rarely increase of weight as the effect of plentiful water-drinking, if not carried to excess as regards quantity and time; the secretions of the urine, bile, saliva, and pancreatic juice, appear to be increased by the abundant internal use of water, as well as the perspiration, though the latter to some degree requires the concomitant influence of high external temperature or bodily exercise.

Water has also an important share in all internal courses of mineral waters. Used by itself, it can exercise some good influence in cases of gout and gravel, in hemorrhoidal complaints, imperfect secretion of bile, and constipation from sluggish peristaltic action. As, however, excessive water-drinking, according to Priessnitz's original plan, is apt to cause dyspeptic troubles, water is now, in general, used internally only either for dietetic purposes, or to assist in other courses of treatment.

The *external use* of cold water admits of a very great variety of applications, and a corresponding variety of effects on the body. The two main effects of the different forms of cold baths are *abstraction of heat*, with its further influences on the functions of the body, and *stimulation of the cutaneous nerves*, and through these of the nerve-centres. Both effects are usually combined, but in some forms of bath, the stimulation or the *exciting effect* preponderates; in others the abstraction of heat, with its *calming or depressing influence*. Hence the different forms of baths, or rather hydrotherapeutic procedures, may be divided into *stimulating* and *calming*, but it is to be borne in mind that there is no strict line of distinction. With this limitation we may regard as *stimulating*—the full cold bath of short duration, the stimulating action of which is increased by motion of the water, be it natural or artificially imparted; the rapid wash-down, either by means of a large sponge or by means of a wet sheet, with or without friction; the spouting of the back, and the pail douche; the needle-bath or circular shower-bath, the different forms of the rain-bath, and the usual shower-bath; the great variety of other douches, and the running or flowing sitz-bath. The immediate effects of these stimulating forms, in a constitution endowed with a certain amount of reactive power, are exhilaration, increased activity of circulation and muscular force, and improved appetite and digestive power. By altering the duration of the bath, and the temperature of the water, the effects may be considerably modified, and thus adapted to different conditions.

The more *calming* forms are—the wet sheet-envelope, entire or partial, the impermobile wet compresses; the full cold bath of long duration and without motion; the sitz, the shallow, and foot baths without motion; and the full bath of higher temperature. Depression through abstraction of heat exceeds the stimulation in these forms: diminution of nervous irritability, of sensation and mental activity, and of the frequency of the pulse and energy of circulation. A feeling of lassitude; and a tendency to sleep, are the principal effects. These forms can, however, be modified, and the effects vary in proportion. Thus the wet sheet-envelope allows ample variation by using warm or cold water, by using the sheet dripping or wrung out, by making the sheet fit tightly round the neck, by moving the sheet to and fro, by frequently changing the sheet, &c. The calming and stimulating form may be further combined by using, first, the wet sheet-envelope, or the woollen blanket-envelope, for a sufficient period to produce perspiration; and then a more or less cold bath or shower-bath of short duration. The physician has, indeed, infinite varieties

of application at his disposal, to be used according to necessity.

Powerful and most important hydrotherapeutic helps are the different vapour- and hot air-baths (Russian, Roman, Turkish baths), combined with douches and baths of various temperatures. These kinds of baths are, however, treated of in another article. See BATHS.

A plain nourishing diet, without or with only a limited amount of stimulants; outdoor exercise in proportion to the strength of the individual, and in some cases active or passive gymnastics, are likewise to be regarded as valuable adjuncts in the hydrotherapeutic treatment of chronic diseases, for muscular exercise means not only increased action, oxidation, excretion, and development of muscle, but also increased general circulation and respiration, increased inhalation of oxygen, and increased production of heat, so necessary in the cold water-cure. There is also no reason whatever why pharmaceutical remedies should not be combined with the water-cure treatment—a method which, as already mentioned, is frequently adopted in the best establishments.

Therapeutic Effects, and Morbid Conditions Suitable for Hydrotherapeutic Treatment.—The principal results of well-adapted courses of cold water treatment are:—improved nutrition and action of the skin, increased tone of the nerve-centres, regulation of the circulation; amelioration of the sanguification and nutrition, and acceleration of the retrogressive tissue-changes. It is essential for such successful results that the organism be able to stand a certain amount of abstraction of heat, that it be capable of more or less energetic reaction; and that the digestive and assimilative organs be able to take up a fair amount of nourishing material, which is required by the increased demand on the body.

Acute febrile diseases.—Amongst the oldest therapeutic uses of the cold bath, though it has only lately been more extensively revived, is the employment of different forms of cold baths in acute febrile diseases, attended with a high degree of pyrexia. The moderately cold or the cooled-down bath, as proposed by Dr. von Ziemssen of Munich, is the form principally employed; but cold affusions, the shower-bath, the wet envelope frequently changed cold compresses, the application of ice in substance, washing with iced water, and iced enemata are likewise applicable; and the liberal internal allowance of cold water forms an important part of the dietetic management of this class of diseases.

Typhoid fever.—Typhoid fever is the disease in which this treatment, with numerous modifications, has been most generally adopted. As soon as the temperature of the patient reaches 102° to 103° Fahr., he is placed in a bath of about 90° Fahr., and the temperature is gradually cooled down, by the addition of cold water, to 80° or 60° Fahr., according to the patient's power of reaction. The patient is kept in the bath generally from 10 to 15 or 20 minutes, when slight shivering often manifests itself. The patient's temperature, measured in the rectum, is usually reduced by this procedure about 1½° to 5° Fahr., not immediately, but within the first hour after the bath. As often as the temperature may again reach 102°

to 103°, the patient is again placed in the bath. Thus, during the height of the pyrexia three to five baths may be required in twenty-four hours, while later on about two are usually sufficient, and often only one. Instead of the bath gradually cooled-down, a bath of a temperature between 60° and 90° Fahr., may be given, according to the condition of the individual patient. The frequent and careful use of the thermometer is an essential element in this method of treatment, which may be, as it often is, advantageously combined with the administration of alcohol, quinine, and other remedies. The earlier the baths are commenced, the greater seems to be their influence in mitigating the severity of the disease and its sequelæ, and in shortening its duration. In the numerous accounts of German physicians (Brand, Ziemssen, Zimmermann, Jurgensen, Liebermeister, &c.) it is claimed that the mortality is considerably less with this than with the expectant or any of the other usual modes of treatment.

Hyperpyrexia.—A still bolder use may be made of the cold-water treatment, in those rarer cases of hyperpyrexia occasionally occurring in the course of rheumatic fever, when the temperature rises to 108° Fahr. and more, and where very cold and prolonged baths, the application of ice-bags, &c., appear to be the only means of saving life. (See Dr. Wilson Fox, *Treatment of Hyperpyrexia*; the writer's case in the *Clinical Society's Transactions*, vol. v., and several other papers in the *Clinical Society's Transactions*.)

Scarlet Fever.—In scarlet fever we have found warmer baths (80° to 98° Fahr.) more generally applicable than quite cold or cooled-down baths, though in cases attended by a high degree of pyrexia and brain-symptoms these are preferable.

Hæctic fever.—In hæctic fever, connected with various chronic diseases, the effect of hydrotherapeutic treatment is less decided, and not yet sufficiently tested.

Digestive derangements of the most different kind, associated with *sluggish venous circulation* in the abdominal organs—conditions which may be grouped together under the term *abdominal remission*, tendency to hæmorrhoids, to hypochondriasis, &c., are often the objects of the water cure, which may be useful by stimulating the physical and psychical energy of the nervous system, as well as the nutrition and tissue-change, by invigorating the skin. Habitual constipation from this cause is often relieved by the hydrotherapeutic belt. In this class of cases the common salt waters, and the alkaline sulphatic waters are more frequently used, and are often preferable, they may, however, be advantageously combined with judicious hydrotherapeutic treatment.

Chronic metallic poisoning may be treated in some cases with equal benefit, if there is sufficient reactive power, at cold water establishments, as at the thermal sulphur and simple thermal spas. The external hydrotherapeutic procedures aiming at increased perspiration and tissue-change, are in this class aided by the abundant internal use of water, in order to wash out the tissues, and especially the liver.

Skin-weakness or atony of the skin is often the cause of frequently recurring attacks of diarrhoea, with neuralgic pains, of tendency to catarrh of

the respiratory mucous membrane, and of rheumatism. Gently stimulating hydrotherapeutic appliances, with gradually increasing energy, are here mostly useful, unless, as in impeded convalescence, the reactive power is so reduced that the gaseous thermal salt baths and mountain-air are preferable, while in others sea-air and sea-baths are successful competitors of the water-cure.

Hysteria.—In hysteria and hysterical affections the water cure has obtained many good results, not by the internal use of water, but by the milder forms of baths. Functional hyperæsthesia and anaesthesia, hemicrania, spinal irritation, intercostal neuralgia, and other forms of neuralgia depending on imperfect nutrition and tissue-change, are likewise often benefited.

Organic diseases of the nerve-centres are not suitable for treatment in cold water establishments, excepting occasionally for palliative purposes.

Rheumatism and gout.—In *muscular rheumatism* the original supporters of the water-cure considered their plan as infallible, but this is by no means the case. The diaphoretic methods, namely, the woollen blanket-puck and the wet sheet-envelope, often prove useful; but we know also of many failures in even good establishments. The exposure to all weathers during the cure ought certainly not to be imitated by such invalids, and the access of cold air to the wet body is to be more carefully avoided than it often is. The course must not be prolonged too much at one time, but may be repeated after an interval of months, which may be spent with advantage at several seaside localities, at moderate elevations, with the help of pine-leaf baths, or at one of the gaseous thermal saline spas.

Rheumatic and gouty swellings of joints require great care in their management. The enfeebled invalid is rarely a fit object for the water-cure; but the stimulating local compress, more or less impermeable, is a useful element in the treatment of such cases.

Milder cases of *gout* may expect benefit from the usual hydrotherapeutic treatment, in so far as it aims at increased retrogressive tissue-change, and invigoration of the nervous system, especially if this treatment is associated with great moderation in the use of stimulants, and also of food in general, but local packing not rarely causes fits of gout. The more serious forms of gout are too much complicated with various defects of constitution to encourage us in recommending cold-water treatment.

Chronic affections of the skin.—In some diseases of this kind, such as prurigo, urticaria, eczema, and local perspirations, a more or less modified hydrotherapeutic treatment is an important adjuvant.

Syphilis.—The favourable results obtained in syphilis, or rather in the often complicated conditions of *lues*, have greatly contributed to the reputation of the water-cure; but the latter is only an excellent adjuvant to pharmaceutical treatment in these cases, in a similar way as the sulphur waters are; and many of the cures of so-called *lues* may be regarded as cures of *mercurialism*.

Catamenial irregularities are not rarely treated

at hydrotherapeutic establishments. Profuse menstruation is often checked by the regular use of the cold hip-bath of short duration, namely, three to five minutes; in insufficient menses, on the other hand, warm hip-baths of ten to fifteen minutes' duration are frequently useful, combined in some cases with the wet sheet-envelope; and dysmenorrhœa is likewise occasionally treated with advantage by the partial wet sheet-envelope.

This list of morbid conditions which may be more or less benefited, might easily be increased, and this is not astonishing if it is considered that hydrotherapeutic treatment can be infinitely modified and adapted to the powers of the constitution; and that it may be assisted by varying hygienic, climatic, dietetic, and pharmaceutical influences; for there does not exist any antagonism between hydrotherapeutic and other rational treatment, the former being, in fact, only part of the latter. Hence, however, it is also evident that the treatment in well-arranged hydrotherapeutic establishments ought to be under the guidance of the most intelligent physicians, just as is the case at all the best spas, indeed the physician at such an establishment ought to be of a very superior kind, possessing in a more than usual degree the gift of recognising all the individual peculiarities of the constitution, especially the amount of reacting power, adapting the principal remedy to every individual case, and combining other elements of treatment with hydrotherapeutic management wherever this is necessary. In the same way as we demand in suitable cases the administration of other remedies together with water-treatment in hydrotherapeutic establishments, so we must also express a wish, that out of such establishments, hydrotherapeutic elements should be more generally combined with the usual medical treatment. For this purpose it is to be desired that well-conducted establishments should be in or near large towns, in order that persons following their usual occupations might undergo certain kinds of treatment at such establishments, or that attendants from such establishments might be sent to the house of invalids. a.i.a., blood).—Excess of blood in a part. See *CIRCULATION*, Disorders of.

HYPERŖSTHESIA (*hŭp*, over, and *asthŭsis*, sensation).—Increased sensibility of a part. See *SENSATION*, Disorders of.

HYPERALGESIA (*hŭp*, over, and *alŭges*, pain).—Undue sensibility to painful impressions. See *SENSATION*, Disorders of.

HYPERIDROSIS (*hŭp*, excessive, and *idros*, sweat).—Excessive perspiration, also termed *adroma*, *ephidrosis*, and *audotoria*. See *PERSPIRATION*, Disorders of.

HYPERINOSIS (*hŭp*, over, and *is*, in, *inos*, flesh).—Excess of fibrin in the blood. See *BLOOD*, Morbid Conditions of.

HYPERMETROPIA (*hŭpemetropos*, beyond all measure, and *hŭp*, the eye).—A congenital or acquired error of refraction of the eye, in which, owing to low refractive power of the dioptric media, or too little convexity of the refracting surfaces, or unnatural shortness of the antero-posterior axis of the eyeball, parallel rays of light do not, while the accommodation is in repose, converge to a focus on the layer of rods and cones of the retina, as in the normal or emmetropic eye, but to an imaginary point somewhere behind it. It is the opposite of Myopia, and is sometimes called Hyperopia or Hyperpresbyopia. See *VISION*, Disorders of.

HYPEROPIA (*hŭp*, above, and *hŭp*, the eye). See *HYPERMETROPIA*.

HYPERPLASIA (*hŭp*, over, and *plasma*, I mould or form).—An excessive growth of normal tissue-elements, which may lead to hypertrophy, or to the formation of distinct tumours. See *HYPERTROPHY*, and *TUMOURS*.

HYPERPRESBYOPIA (*hŭp*, above, *presbus*, old, and *hŭp*, the eye). See *HYPERMETROPIA*.

HYPERPYREXIA (*hŭp*, excessive, and *pyrexia*, fever).—Excessive pyrexia. See *FEVER*, and *TEMPERATURE*.

HYPERTROPHY (*hŭp*, over, and *trophŭ*, nourishment).

DEFINITION—The word 'hypertrophy' signifies excessive nourishment, but is in practice used to designate the result of excessive nourishment, that is, excessive growth. Hypertrophy may be general or partial.

I. General Hypertrophy.—General hypertrophy, though a remarkable condition, is of little practical importance. It is known only in those individuals of enormous size, who are called 'giants.' The production of giants depends on causes entirely unknown, since it is noticeable that this condition commonly affects only one in a family, and is in its most conspicuous forms not hereditary. Giants are usually of feeble constitution, and deficient in procreative power. The name *macrosomata* has been given to a condition equally unexplained, in which the whole body becomes enlarged in a monstrous degree. This condition has been observed to be in some instances congenital, or, at least, to begin in very early life. True general hypertrophy does not appear to be capable of being produced by any artificial means, since excessive feeding either

produces hypertrophy almost confined to one tissue, namely, fat, or else fails to produce any enlargement at all.

II. Partial Hypertrophy.—By this is meant (a) excessive increase of any part of the body during the period of natural growth, either in intra-uterine or extra-uterine life; or (b) increase of a part already completely formed. According to this distinction hypertrophy may be classified as *congenital* or *acquired*.

1. CONGENITAL HYPERTROPHY.—Congenital hypertrophy is that condition in which some part of the body begins from the first to grow so rapidly as to attain a size far beyond the normal. This condition has been seen to affect one side of the body, or one limb only, which thus becomes much larger than its fellow on the other side. Such a condition might be in theory difficult to distinguish from atrophy of the opposite side, or of the other limb, that is, from *hemiatrophy* (*see* **ATROPHY**); but in general the hypertrophic side is so far beyond the normal size as to prevent ambiguity. One remarkable case is on record in which one leg and arm assumed the proportions of those of a giant, whilst the other remained unaltered. Sometimes a congenital hypertrophy occurs without this unilateral character, as in the case reported by Mr. Curling of a girl aged fifteen, who had several fingers of both hands enlarged in an extraordinary degree without any assignable cause, the equality of the two sides being nevertheless preserved. Such instances, although unexplained, must, it would seem, be put into the same class as the gigantic growth of the whole of the body. Hypertrophy of special tissues is also sometimes congenital, as of the skin in *ichthyosis*. Hypertrophies similar to those here called congenital may occur, though rarely, in adult life. The enlarged part is found to be highly vascular, to have an increased temperature, and to preserve its normal proportions. The cause in these cases is equally unknown.

2. ACQUIRED HYPERTROPHY.—Acquired hypertrophies appear to result, roughly speaking, from the following causes:—(a) increased work, (b) pressure, (c) inflammation, (d) increased supplies of nourishment; or (e) physiological changes.

(a) *Increased work.*—Increased use of the part can produce hypertrophy only in those organs which have an active function, especially the muscles. It is a matter of familiar observation that voluntary muscles increase in size when much employed, as is seen in the often mentioned arm of the blacksmith or the leg of the ballet-dancer. In order to produce this increase, the exercise must be of a certain degree of intensity, but not excessive. It must be frequently repeated, with intervals of rest, and at the same time the nutrition of the whole body must be good. In the absence of these conditions, exercise is more likely to produce wasting. The explanation of this familiar process is still obscure.

Hypertrophy of the heart occurs in cases where that organ is made to work at a higher tension than the normal, and this higher tension can only result from increased resistance to the flow of blood, either at the orifice of the heart, or in the peripheral vessels. Hence the conditions most commonly giving rise to it are valvular disease, especially stenosis, and obstruction of the arteries,

either by the thickening of their walls, or by contraction of their muscular coats. The right side of the heart will also become hypertrophied when any condition whatever hinders the passage of blood through the lungs. Disease of the kidneys is a frequent cause of enlargement of the left ventricle of the heart, though in what way is still a matter of discussion. It is only quite clear that the kidney-disease in some way increases the resistance in the smaller arteries and capillaries.

Hypertrophy of the smooth or involuntary muscular fibres also occurs whenever that tissue has to contract for a long period under a higher tension than the normal. Thus the walls of the bladder become thickened in cases where, from obstruction of the passages, the evacuation of urine is effected with more difficulty, and under a higher pressure, than usual. In the same way the walls of the stomach, the œsophagus, and intestines become hypertrophied in cases of obstruction to the passage of food through the alimentary canal.

The explanation commonly given of these cases of hypertrophy in the contractile organs is, that in consequence of obstruction the organ has to contract with greater force than usual, and thus becomes hypertrophied in the same manner as a voluntary muscle, which is frequently exercised. It is, however, clear that this so-called explanation does not account for the connection between obstruction and more powerful contraction. The only explanation that can be given is that in these cases pressure or tension on the organ itself is the stimulus to contraction, and that the force of contraction appears to depend roughly upon the strength of the tension which produces it.

There is less evidence that nervous or glandular structures undergo hypertrophy in consequence of their increased use; but if one kidney be destroyed the other is generally enlarged; and some authorities believe in an increase in the size of the brain from mental activity.

(b) *Pressure.* Pressure appears to produce hypertrophy only when it is moderate and intermittent. Excessive or continuous pressure rather produces atrophy. Thickening of the epidermis from external pressure is the most familiar instance. Pressure perhaps, leads to hypertrophy by causing an increase of the flow of blood.

(c) *Inflammation.*—Inflammation when chronic is a cause of hypertrophy in some of the tissues, more especially in various forms of connective tissue. This is constantly the case in chronic interstitial inflammation of solid organs, in which indeed it is impossible to draw the line between inflammation and fibrous hypertrophy. But it should be remembered that this condition is usually accompanied by atrophy of the other tissues, so that the size of the organ itself is more likely to be diminished than increased. The serous membranes, as the pleura, peritoneum, and dura mater, become thickened from chronic or repeated inflammation. Thus pericystitis is a frequent cause of hypertrophy of the lungs. The skin also becomes thickened in chronic eczema, and this condition may

extend to the subcutaneous tissue. Acute inflammation, on the other hand, is more likely to produce wasting of the organ it affects.

(d) *Increased nourishment*.—It must be regarded as doubtful whether increased nourishment alone is capable of producing enlargement of any part of the body. It certainly does not necessarily do so, as is shown by the case of experimental hyperæmia. When this condition is produced, for instance, by section of the cervical sympathetic nerve, in one side of the face and head of an animal, hypertrophy is only a rare and occasional consequence. When, however, the increased supply of nutrition in the form of blood is combined with some irritation or functional stimulus, we often find hypertrophy result. Thus, for instance, reflex hyperæmia of the skin of the face or blushing, which is produced by numerous internal causes, such as gastric or uterine derangement, may subsist for years and reach a very high degree without altering the nutrition of the part. But if there should be in addition some disturbance or inflammation of the glands of the skin, we have the conditions called *acne rosacea*, &c., in which hypertrophy is an important element. Almost the only instance that can be quoted of hypertrophy from increase of blood-supply alone is that of the corpus luteum during pregnancy, when the ovary participates in the functional hyperæmia of the uterus. The well-known experiment of Hunter should also not be forgotten, in which he transplanted the spur of a cock from its foot to its head, and found it to increase in size.

It is, however, important to remember that hypertrophy, however produced, is always accompanied by an increased supply of blood, and enlargement of the vessels.

(e) *Physiological changes*.—Physiological hypertrophies form an important class. One of the best instances is that of the enlargement of the uterus during pregnancy. This enlargement is clearly not the consequence of hyperæmia alone, nor of increase of the functional activity in the muscular walls, though both these conditions are present, but must proceed from some direct physiological stimulus like that which determines the growth of the embryo itself. The hypertrophy affects all parts of the organ—its mucous and serous coats, as well as the muscular walls. Enlargement of the mamma appears to arise from similar causes, and it is even probable that swelling of the thyroid may, through some obscure connection with the sexual organs, be caused in the same way. Some instances of hypertrophy we cannot in any way explain, such as the apparently spontaneous enlargement of the tonsils, spleen, and thymus gland, which are sometimes observed. The same is true of the enlargement of the prostate which is so common in old age. These changes have been sometimes explained by a supposed derangement of the so-called *trophic nerves*, but this explanation only puts the difficulty a little further back.

Process of Hypertrophy.—It has been a question whether hypertrophy depends upon the increase in the size of the minute elements of an organ, or only on increase of

their number. There can be no doubt that the former change often occurs. Thus, in the pregnant uterus the muscular fibres have been found from seven to eleven times as long as natural, and from twice to seven times as wide. In a remarkable case of enlargement of the nerves, described by Dr. Moxon, the nerve-fibres were found to be on an average three times and some of them even forty times as large as normal. When enlargement of one kidney takes place as a consequence of destruction of the other, the tubules and Malpighian tufts are found greatly increased in size. In hypertrophy of the heart, the muscular bundles are found to be thickened, though the fibrillæ are unchanged, but in most cases multiplication of the tissue-elements is the chief cause of the increase in size. To this latter process Virchow gives the name of *hyperplasia*, and it is important to remember that, though constantly occurring in hypertrophy of organs, it does not necessarily lead to the latter change.

False Hypertrophy.—We sometimes have to distinguish between *true* and *false* hypertrophy, meaning by the latter a process in which an organ becomes outwardly increased in size, owing to the deposition within it of some foreign material, or to mere distension. Thus in a fatty liver the real liver-tissue is wasted, but is replaced by fat. An emphysematous lung appears to be increased in size, but has actually suffered atrophy. The substance of the brain in hydrocephalus may be greatly reduced in volume, though the head appears of enormous size. The very remarkable disease called 'Duchenne's Paralysis' is an instance of apparent hypertrophy of the muscles, through deposition of fat between the fibres. Finally, it should be remembered that hypertrophy is not necessarily a progressive or permanent condition, but may be only a stage in some chronic morbid process of which the termination is atrophy. This is very clearly seen in the process called 'fibroid degeneration,' elsewhere described.

TREATMENT.—No general rules can be laid down for the treatment of hypertrophy. When it is connected with increased functional activity, it is usually a favourable rather than a hurtful condition, though in some cases it may appear that the hypertrophy more than compensates the deficiency or irregularity by which it is produced. But even if this be so, the cure of excessive hypertrophy is not within our powers. Those forms of hypertrophy which are most likely to be injurious or fatal are unfortunately those of which the origin and conditions are most obscure, such, for instance, as enlargement of the prostate, the thyroid, or the spleen. The only hypertrophic condition which appears to be, generally speaking, amenable to treatment is that of fibrous thickening. Whenever the thickened fibrous tissue is accessible to direct treatment, we may probably be able to produce a beneficial effect by the application of counter-irritants, or by special stimulants, such as iodine. The administration of iodine or iodide of potassium internally also has a remarkable, and as yet unexplained effect in many such cases. It is, however, well to point out that when functional hypertrophy has resulted from some obstacle

or undue resistance, it may entirely subside when that resistance is removed. Thus if the uterus have enlarged around a fibrous tumour, it may regain its normal bulk when the tumour is removed; and we sometimes see a sensible diminution in the size of a hypertrophied heart when the derangements which produce it no longer act. Moreover, hypertrophy may be completely reduced by a general lowering of the nutrition of the body. Thus, in early stages of pulmonary phthisis, the heart may be hypertrophied, but when death occurs in a late period of the disease, the organ is rarely found enlarged, and is even wasted, though, according to Dr. Leacock's tables, less so than in other wasting diseases. J. F. PAYNE.

HYPINOSIS (*ὕπνῳ*, under, and *ἰς*, into, flesh). Deficiency of fibrin in the blood. See BLOOD, Morbid Conditions of.

HYPNOTIC (*ὕπνος*, sleep).—Measures that induce sleep. See NARCOTICS.

HYPNOTISM (*ὕπνος*, sleep).—A synonym for Braidism. See BRAIDISM, and MESMERISM.

HYPOCHONDRIAC REGION (*ὕψ*, under, and *χόνδρος*, a cartilage).—This region is double, right and left, occupying the upper part of the abdomen on either side of the epigastrium, and partly corresponding to the lower regions of the chest, being almost entirely covered in by the ribs and their cartilages. Each hypochondrium is bounded below by a horizontal line at the level of the ninth costal cartilage; and internally by a vertical line from the eighth cartilage downwards. The organs situated in the right hypochondrium are the liver and gall-bladder mainly; with, more deeply, the pyloric end of the stomach, part of the duodenum, and the hepatic flexure of the colon. In the left region lie the spleen, a small portion of the left lobe of the liver, the fundus of the stomach, the tail of the pancreas, and the splenic flexure of the colon. The gastro-splenic fold of peritoneum, with its vessels, passes from the stomach to the spleen.

CLINICAL INVESTIGATION.—It must be borne in mind that morbid conditions within the chest not uncommonly originate clinical phenomena, both subjective and objective, in connection with one or other hypochondriac region, and these must always be taken into consideration when investigating any particular case. In making a diagnosis, no reliance whatever can be placed on mere secretions referred to these regions, but physical examination is in every instance required, in order to determine the conditions present, and especially palpation and percussion. Moreover, it must be remembered that disease of an important and serious nature may arise without the occurrence of any unusual feelings. Pain of various kinds is often complained of, and when referred to the right hypochondrium is usually supposed to be connected with the liver; but it may depend upon affections of the superficial structures; peritonitis; right pleurisy or pneumonia; or conditions associated with the pylorus, duodenum, or colon. A characteristic pain starting from this region is that of hepatic colic, usually due to the passage of a gall-stone. Persons who are hypochondriacal not uncommonly refer

some abnormal sensation to their right hypochondrium, for which there is really no obvious cause. In the left hypochondrium pain may also be due to affections of the walls, or of structures within the thorax; of the cardiac end of the stomach; of the colon; or, in exceptional cases, of the spleen.

The morbid conditions which are capable of originating abnormal physical signs in the hypochondriac region may also be either thoracic or abdominal. Of the former, pleuritic effusion is the most frequent; and on the right side this condition may cause marked depression of the liver. In exceptional instances the heart is so enlarged as to reach the left hypochondrium; and the writer has met with a case in which a large thoracic aneurism presented in this region. As regards abdominal diseases in the right hypochondrium, abnormal physical signs are usually associated with the liver, which is altered in position, shape, size, or physical characters. Occasionally they are connected with the abdominal walls; the gall-bladder; or the stomach, duodenum, or colon. On the left side enlargement of the spleen is the main condition discovered by physical examination; but the stomach may also give signs of distension in this direction, or of organic disease of its walls. Exceptionally the colon may present abnormal physical signs. Growths may originate here in connection with the peritoneum, and the writer has recently had under observation a case in which a growth started from the left hypochondrium, probably of a malignant nature, and involving more than one structure, but it was impossible to say where it commenced. Of course the hypochondria are involved along with other regions in general enlargement of the abdomen; and organs from other regions may so increase in size in certain diseases as to extend into one or both of these regions.

FREDERICK T. ROBERTS.

HYPOCHONDRIASIS (*ὕψ*, under, and *χόνδρος*, a cartilage).—*ΣΥΝΟΝ.*: Fr. *Hypochondrie*; Ger *Hypochondrie*.

DESCRIPTION.—The term hypochondriasis is derived from an ancient hypothesis that the symptoms of this disorder were due to perturbations of natural forces generated in the liver and pylorus, to which idea the frequent prevalence of flatulence in the disorder conduced. The condition thus called is really a disease of the nervous system. It is a form of mental unsoundness closely allied to melancholia, of which, indeed, it often forms the initiatory stage. It is characterized by a morbid anxiety, either without any, or having only very slight foundations, relative to the state of physical health. The patient thinks about his health unduly, observing himself with restless care, examining especially the characteristics of his secretions, translating into evidence of progressive organic mischief every trivial departure from perfect action of his organs, and becoming more and more absorbed in precautions against the malady with which he believes himself affected. Nothing that happens tends to the side of reassurance. If his sleep be disturbed, the symptom may be portentous, he thinks, of brain-softening; if it be sound, the patient, instead of being comforted, fears apoplexy. Constipation of the bowels signifies

obstruction; a slight diarrhoea implies coming exhaustion. Everything which he reads or hears in reference to disease, the patient applies to his own case, examining himself on every point thus presented to his mind, and rarely failing to find something which dovetails with symptoms of his own. For he recognises only the points of resemblance; the features of difference are unconsciously ignored. In some cases the patient is constant in referring his troubles to one particular organ. Year after year his story is the same; it is his stomach, liver, brain, or some other organ which is in fault; but always the same. In other instances there is a vacillation quite as remarkable. Routed, perhaps, by the convincing arguments of his adviser, he is forced to yield the position which he had assumed, but only to take an equally strong one in reference to some other part of his frame. These diversities strongly recall the fixed and shifting delusions of insanity. He is prone to wander from one doctor to another, often carrying with him a bundle of prescriptions and a long written list of questions, which must receive categorical answers. Apparently satisfied at the time, he speedily recollects some point upon which he has not received assurance, and thus he conceives vitiates the whole of the explanation and advice which have been given to him, and he is plunged again into his previous state of anxiety and doubt. Where circumstances do not involve forced labour for existence, the patient passes his time in chasing his health, which is always contriving to elude his grasp. If he holds an appointment, he will resign it in order to have full opportunity for studying himself, and his occupation once gone, he finds too late that it was his best friend, and he then ascribes to his forced idleness all the ills which had induced him to seek re-ment.

In many cases the most careful examination can discover no signs of disease, and the patient wears the aspect of health, or there may be a worn, anxious look. In others there may be, especially in the digestive organs, slight deviations from perfect integrity, which explain some of the symptoms, but not the exaggerated apprehensions to which they give rise.

Hypochondriasis is a chronic disorder. It may continue, and this most frequently, as a harmless peculiarity attached to a life which is not perceptibly shortened in length, though often sadly diminished in utility and happiness, by its symptoms. Or there may be an improvement practically amounting to a cure, which will endure for a longer or shorter period. In the decline of life, however, there is very apt to be a return of symptoms. Or hypochondriasis may pass into true melancholia, and then the bodily health, previously the constant object of solicitude, improves wonderfully. Indeed, nothing more is heard about it.

Ætiology.—Hypochondriasis is very much more common in the male than the female sex. The period of life most prone to it is from 20 to 40 years of age. It is apt to occur in those who inherit a tendency to insanity, and the disease in its own peculiar form is often hereditary. Numerous of various kinds, especially on the side of the central system, will precipitate the ap-

pearance and intensify the symptoms of the affection, but it is doubtful whether they can altogether originate it. The same may be said of gout, which is apt to be associated with the condition and to complicate its symptoms. Depressing moral circumstances also are not without influence in determining an onset of hypochondriasis in those predisposed. This is especially true of mental strain. The frequent occurrence of some deviation from healthy condition in the liver, stomach, or bowels, which is noted in these cases, would suggest that, probably through an interruption to the perfect nutrition of the body, disunion of these viscera bear their part in the causation of hypochondriasis. The intercurrentness of internal hemorrhoids with bleeding is very common, and this would manifestly tend to keep up if it did not originate the disease. Stricture and chronic ulcer of the intestines are occasionally associations which probably also influence the appearance of hypochondriasis.

ANATOMICAL CHARACTER.—There are no anatomical characters peculiar to the disease.

DIAGNOSIS.—When careful examination, which must never be omitted, has disproved the existence of organic disease tending to produce the symptoms described by the patient, it sometimes becomes a question whether the case be one of hypochondriasis or of melancholia.

In the former there is no tendency to suicide; on the contrary a strong desire to live pervades the sufferer's mind, and impels him to endless search for the cure of his ailments. He delights in consulting medical men and entering into the minutest details which he thinks can aid them in helping him. Up to a certain point his story is frequently characterised by a logical accuracy, which fails him, however, in some point of great importance, by which the conclusions are invalidated. The melancholic patient, on the other hand, is often suicidal and always desponds of any relief to his condition, the description of which as given by him is confused, frequently incoherent, and unintelligible.

PROGNOSIS.—Early and marked hypochondriasis occurring in a person with a strong hereditary taint of insanity, without any definite cause of mental depression, is of ill omen. Such a case very often drifts into melancholia.

The prognosis is favourable, perhaps, the less strongly marked the hereditary predisposition and the more evident and adequate the immediate causes to which the patient has been exposed, the most potent of which are sexual or alcoholic excesses, mental strain or shock, or the sudden change from a life of activity to one of forced and, as the sequel shows, uncongenial leisure.

TREATMENT.—Moral treatment is almost of any influence in a large majority of cases. Where there is, however, manifest anemia, a history of syphilis, evidences of gouty mal-assimilation, accumulation of feces, catarrh of the intestinal canal, or hemorrhoids, the therapeutics proper to these conditions should be employed. Alcoholic stimulants should be avoided. Travel, especially under judicious companionship, and the encouragement of regular, definite, and useful employment for the attention and the physical powers, are the most potent means of treatment, by which the disease may be often much ame-

torated, and sometimes cured. Radicals of the patient's sufferings will rarely or never be of service, but at the same time a habit of prescribing for all the symptoms as they arise must be avoided.

T. BOWMAN.

HYPODERMIC INJECTION (*brb*, under, and *derma*, the skin).—The effective introduction of remedial agents into the system by subcutaneous injection was rarely possible until the discovery of the alkaloids enabled us to administer an active dose in very small bulk. Dr. Alexander Wood, of Edinburgh, undoubtedly deserves the credit of bringing this principle practically before the profession; and, improved as it has been by Mr. Hunter and others, the hypodermic method is now justly regarded as one of the most active and reliable of our therapeutic resources. It may be used in two essentially different ways.

I. The remedy is thrown into the *subcutaneous cellular tissue* by means of a sharp-pointed hollow needle, attached to a carefully graduated glass syringe. The little prick must be made as rapidly as possible, either by direct puncture, or in a more valvular direction, through a pinched-up fold of skin; and care must of course be taken to avoid the neighbourhood of all important structures. The solution employed must be small in quantity and bland in quality, and must be slowly introduced, as pain usually follows the too sudden or forcible depression of the piston; and we must satisfy ourselves before we begin to inject, that the point of the instrument has passed fairly through the skin, without imbedding itself in the substance of the muscles. When carefully performed, the advantages of this plan are great, for not only is it economical, drugs administered in this way acting much more powerfully than when given by the mouth; but absorption is very rapid, and the desired effect is swiftly and surely produced. The drawbacks of the hypodermic method are—the pain of puncture (which may be alleviated by a slight preliminary freezing of the skin); an occasional tendency to irritation and the formation of abscess; and, where morphia is concerned, the risks of nausea and syncope, and the dangers attending the not very remote possibility of acquiring opium-eating habits.

The principal drugs used hypodermically in this way are the following:—

1. *Morphia*.—Morphia thus administered forms by far our most effectual remedy for the relief of suffering. In all varieties of neuralgia, in the wearing agony of cancer and other incurable disorders, as well as in a host of painful and irritative affections, we derive invaluable aid from the use of the hypodermic syringe: remembering that the dose must at first be small, not exceeding $\frac{1}{4}$ of a grain, and that we derive no special advantage from injecting directly over the spot where the uncomfortable sensations are felt. Recollecting also the occasional occurrence of sickness and faintness, we shall do well to enforce the recumbent posture; to keep our patient under observation for a few minutes after the operation is over; and perhaps to combine $\frac{1}{100}$ grain of atropia, which seems to have in some measure the power of preventing the depressing action which morphia occasionally displays when administered alone.

2. *Atropia*.—Austie had great faith in atropia, as the best of all remedies for pain in the pelvic viscera; and its injection hypodermically has been attended with good results in the nocturnal sweating of phthisis in doses of $\frac{1}{100}$ to $\frac{1}{50}$ grain; and also as an antidote in opium-poisoning, even up to half-a-grain.

3. *Ergotina*.—Ergotina acts most effectively in cases of hæmorrhage, its chief disadvantage being the development of black painful lumps at the site of puncture. The average dose is 2 grains.

4. *Quassia*.—This useful drug has been extensively used in tropical climates by hypodermic injection for ague, sunstroke, &c.; but the great pain attending the operation, and the subsequent liability to the formation of abscess, have proved effectual barriers to the general introduction of the practice into this country.

5. *Other drugs*.—Chloral, where subcutaneously used, also causes severe suffering, with the production of unhealthy ulcerations of the skin. Many persevering attempts have been made, but have not yet been successful in overcoming the very irritating effects of mercury when employed in this way. Out of the large number of other drugs, the subcutaneous use of which has been tried from time to time, we are unable to report any substantial advantage thus gained over their administration by the mouth.

II. The second hypodermic method is that recommended by Bartholin and various American and Continental physicians, and usually called the *deep or parenchymatous* method. This essentially consists in plunging the point of the needle into the muscles, and forcing the fluid freely amongst their fibres, and into the immediate neighbourhood of painful nerves. We are told that in this way chloroform is a very certain remedy for neuralgia; that strychnia is indicated in infantile, reflex, hysterical, and lead palsy; and that carbolic acid is useful in erysipelas. As yet, however, there is not much British experience to quote in confirmation of this practice.

In conclusion, we may note that most hypodermic solutions are readily destroyed by mould; and that Dr. Sansom has suggested a very handy series of gelatine disks, which will keep well in all climates, and which may readily be melted down when required for use.

ROBERT FARQUHARSON.

HYPOGASTRIC REGION (*brb*, under, and *gastri*, the belly).—The hypogastric region is conventionally described as lying between the right and left inguinal, below the umbilical, and above the pubic regions.

ANATOMICAL RELATIONS.—The surface of the hypogastric region in ordinary persons is flat, showing the muscular reliefs; it is rounded in children; and in some individuals, much emaciated from disease, it becomes concave.

The median furrow disappears below the umbilicus, owing to the approximation of the recti muscles.

The integument is very elastic and movable, especially at the sides.

The superficial fascia consists of two laminae, between which lie the subcutaneous vessels; but in the middle line these laminae are blended.

is strengthened at its lower part by the *triangular fascia*.

The *sponsosures* of the external and internal oblique muscles are united in the *linea alba*, and form a portion of the *sheath of the rectus*.

The *recti muscles* themselves have their inferior attachments in this region, along the line extending between the spine and the symphysis of the pubes; their outer edges curve outwards, and become straight as they enter the sheaths.

The *pyramidales*, two small triangular muscles, arise from the pubes, lie in the same sheaths as the recti, and assist in closing in the abdominal parietes anteriorly and below.

Immediately beneath the recti is the *fascia transversalis*, with a little loose areolar tissue and fat, the fascia being tolerably adherent along the central line. Beneath the fascia transversalis there is a considerable amount of loose areolar tissue, between it and the *parietal peritoneum*, which in this region is very loosely attached, and reflected off the bladder on to the fascia transversalis. Enclosed in folds of the peritoneum lie, on either side, passing upwards to the umbilicus, the remains of the hypogastric arteries; and from the apex of the bladder in the middle line, passing to the umbilicus, is the obliterated urachus, which acts as the superior ligament of the bladder.

The *viscera* corresponding to the hypogastric region are:—the bladder when full, and the *small intestine*, covered by the *great omentum*. When the bladder is full, the intestines are pushed aside, and the former then lies against the pubes and recti. In children the bladder, being an abdominal rather than a pelvic viscus, always lies in this region. During pregnancy the uterus also corresponds with the hypogastric region.

The *vessels* are the deep epigastric, with the *aorta* which pass obliquely inwards from the internal iliac. They lie between the peritoneum and the transversalis fascia.

The *nerves* are derived from the lower intercostals and lumbar. The *lymphatics* pass into the inguinal, superficial pubic, and lumbar glands.

CLINICAL RELATIONS.—The hypogastric region is of clinical importance chiefly from an operative point of view. It is in the median furrow of this region that the operation of tapping in ascites is usually performed; and that the principal incision is made in ovariotomy, the Cæsarian section, and supra-pubic lithotomy. The bladder is occasionally tapped above the pubes. The presence of the distended bladder or of the pregnant uterus, forming a tumour in the hypogastrium, has been already referred to. Enlargements here from these causes have to be diagnosed from pelvic tumours of various kinds, which, in growing upwards into the abdomen, occasionally occupy the middle line instead of either groin. The only morbid condition of the abdominal parietes in the hypogastric region that requires special mention is abscess connected with disease of the lumbar spine, which occasionally points above the pubes, on either side of the middle line. The pus in such a case is situated between the peritoneum and the fascia transversalis.

EDWARD BELMONT.

HYPOGLOSSAL NERVE. Disorders of. The hypoglossal nerve is the motor nerve for the tongue, and for most of the other muscles which are attached to the hyoid bone, the exceptions being the stylo-hyoid, the mylo-hyoid, and the middle constrictor of the pharynx. It also supplies the sterno-thyroid muscle.

1. Paralysis.—Paralysis of this nerve is shown chiefly by the resulting interference with the movement of the tongue—'glossoplegia.'

ÆTIOLOGY.—The nerve may be damaged in any part of its course by the growth of tumours; but is most commonly affected at its origin within the spinal canal, by pressure from tumours, meningitis, or syphilitic growths, or by caries of the upper cervical vertebrae. The tongue is also paralysed by disease of the nucleus of origin of the hypoglossal fibres, but its paralysis is then associated with that of the lips, and commonly also of the palate, pharynx, and glottis (see LARYNGO-STYLOGLOSSAL PARALYSIS). Disease of the motor tract above the nucleus also causes paralysis of the nerve, together with the face, arm, and leg of the same side. Bilateral glossoplegia commonly results from disease of the nucleus or its neighbourhood. Unilateral paralysis is due to disease of the motor tract above the nucleus, rarely of the nucleus itself, often of the fibres of the nerve within or outside the medulla.

SYMPTOMS.—In unilateral paralysis, the tongue at rest is in its normal position in the mouth, but its root is higher up on the paralysed than on the normal side, in consequence of the loss of the tonic, or voluntary, contraction of the posterior fibres of the hypoglossus. Within the mouth the tongue is moved freely to the healthy side, but is not moved to the paralysed side. When protruded it deviates towards the paralysed side, because the protrusion is the result of the action of the fibres of the genio-glossus, and the tongue is pushed over towards the weaker side. In bilateral paralysis the tongue lies in the mouth behind the teeth, and cannot be protruded. If the loss of power is complete, the tongue cannot be projected over the lower teeth. It is broad and flabby, if there is no atrophy, and sometimes when atrophy is associated with fatty overgrowth. When there is much wasting, the part affected is shrunken and wrinkled. In unilateral paralysis, articulation and deglutition are little impaired. The pronunciation of labials, and the production of falsetto notes may, however, be difficult. In bilateral paralysis, articulation is impossible. Phonation is not impaired, unless the larynx is also paralysed. The mastication of food is impeded, because the food cannot be moved about the mouth. Deglutition is also interfered with, because the food cannot be rolled into the fauces; and soft foods, when they reach the pharynx, may be driven again into the mouth in consequence of the absence of the natural supporting movement of the tongue. Taste is not primarily affected, but may be somewhat dulled, because the patient is unable to move substances about the mouth.

DIAGNOSIS.—The position of the lesion is indicated by the associations of the paralysis. If the disease is in the motor tract above the nucleus (pons, crus, or hemisphere), there is hemiplegic weakness on the side of the paralysis

of the tongue. In disease of the nucleus the paralysis is commonly bilateral, is associated with paralysis of the lips and throat, and there is usually wasting. Disease of the fibres of origin within the medulla is associated with paralysis of the opposite limbs, so that the tongue deviates from the paralysed side. When the disease is at the surface of the medulla, the paralysis is commonly unilateral, and is associated with paralysis of the corresponding half of the palate and vocal cord (Hughlings Jackson.) In disease of the fibres of origin within or outside the medulla, there is commonly wasting. The diagnosis of the pathological cause of the paralysis rests on the course of the affection, and on the presence of any causal and associated condition.

PROGNOSIS.—This is usually unfavourable, on account of the gravity of the disease which damages the nerve or centre. Even in syphilitic cases, recovery is often incomplete.

TREATMENT.—The treatment of paralysis of the hypoglossal nerve is that of the causal disease. Tonics, counter-irritation, iodide of potassium and mercury, with occasionally the application of electricity to the tongue, are the most important remedies to be employed, according to the ætiological indication. The most convenient method of applying electricity is by means of a tongue depressor in a wooden handle, the blade being insulated by a coating of sealing wax where it comes in contact with the lips.

2 **SPASM.**—Spasm in the parts supplied by the hypoglossal nerve is rare. The tongue participates in the convulsive movements in epilepsy, is jerked between the champing jaws, and thus becomes bitten. Cases have been met with in which the tongue is affected with a 'functional spasm' in speaking, analogous to 'writer's cramp,' but these are so rare as scarcely to need detailed description. W. R. GOWEN.

HYPOSPADIAS (*ὑπό, under, and σπᾶδις, a spade*).—A malformation of the penis in which the orifice of the urethra is underneath or behind the glans. See MALFORMATIONS.

HYPOSTASIS (*ὑπό, under, and στάσις, I stand*).—DEFINITION.—This term is applied to that condition of the vessels of a part, which consists in an overfulness, caused mainly by a dependent position, with a varying degree of diminution in the rate of flow of the contained fluid.

PATHOLOGY.—The entire conditions of the venous circulation are such as to readily favour a stasis or stagnation of the blood-flow; and a trifling cause, such as would in no way affect the arterial flow, may easily impede the venous current. The veins also are, as a rule, less firmly supported by the surrounding tissues than the arteries; and this, with their thinner coats, slighter elasticity and resistance, render them easily liable to distension by the blood in congestion. If a dependent position be added to these conditions, thereby offering a resistance to the return flow of the blood, whilst it favours the circulation in the arteries, a combination of circumstances exists to which the term *hypostatic congestion* is applied. The liability of the veins of the leg to become congested,

leading to a varicose condition and its results, is an example of this state. If, in addition to all these factors, the heart be enfeebled and the arterial tone be diminished, obviously another cause for stagnation is introduced, and of necessity will manifest itself most in those situations predisposed to stasis. Such a state is seen in the hypostatic congestion of the lungs, which usually attends in a greater or less degree all pyrexial conditions. The recumbent attitude, the enfeebled heart, and the lax vessels eminently favour an overfulness of the veins. It is obvious that although the excess of blood primarily occurs on the venous side of the capillary system, very soon the arterial area will share in the engorgement, and the whole vascular system of the part become overfilled.

RESULTS.—The pathological results of such a state are very much the same as those following any congestion. The distended vessels, with the increased blood pressure that co-exists, readily permit of a transudation of the fluid part of the blood, hence œdema; if the conditions be extreme, capillary rupture may take place, and hæmorrhagic effusions result. Any continuance of this state will lead to malnutrition of the tissues affected, the proper supply of arterial blood is interfered with; and the part is loaded with an effete venous blood, and infiltrated with serum. Hence the structural repair of the tissues is improperly performed, and there is a tendency to the development of an imperfect form of connective tissue; or, on the other hand, the destructive rather than the productive aspect may predominate, and ulceration follow. When the hypostasis is associated with an acute general state, as of the lungs in any specific febrile disease, it is very apt to pass on into a form of inflammation characterised by a want of acuteness. There are the same inflammatory products, the same changes in the vessels and tissues of the lungs, and very much the same symptoms as occur in the course of an ordinary pneumonia, but they are less severe in character, and on the whole do not tend so readily to a favourable resolution.

TREATMENT.—Recognising the cause, alteration of position is obviously the rational treatment of hypostatic congestion; additional support by bandaging is often advisable. In acute febrile diseases stimulants are of much service in the prevention or relief of this condition in connection with the lungs, should the heart's action be enfeebled. W. H. ALLCHIN.

HYSTERALGIA (*ἡστέρα, the womb, and ἄλγος, pain*).—Pain in the womb, frequently supposed to be of a neuralgic nature. See WOMB, Diseases of.

HYSTERIA (*ἡστέρα, the womb*).—SYNON.: *Fr. Hystérie; Ger. Hysterie.*

Hysteria is a term the etymology of which is misleading, and had best, therefore, be disregarded. It is often improperly applied to cases of simple malingering, and others which do not admit of ready explanation. Its use is best restricted to a condition of the nervous system fairly defined, but the intimate pathology of which is not known, characterised by the occurrence of convulsive seizures and by departures from normal function of various organs, leading to very numerous and

often perplexing symptoms. These are apt to simulate those commonly arising from definite alterations of structure, but differ from the latter in the fact that they may often, even when at their worst, be removed instantaneously, usually under the influence of strong emotion. It would seem that there is a disturbed or congenitally defective condition of the cerebral substance, involving in all cases the highest nervous centres, and in various examples extending more or less also to some of those which preside over automatic phenomena. Partial or complete suspension of inhibitory influence would appear to be the most patent result of the condition, whatever it be, and this is recognised as well in regard to the mental as to the more evidently physical processes belonging to cerebral function. A laugh which cannot be checked, but continues until tears flow, or the limbs become convulsed, is a typical example of such a suspension of control, and, if studied, throws light upon the nature of a considerable portion of the phenomena of hysteria. The jerking expirations of laughter arise from excitation of the respiratory centre, and when this excitation, uncontrolled by higher centres, acquires an abnormal strength, it extends to other parts of the medulla oblongata and spinal cord, and produces general convulsions. It overflows, as it were, into other nervous centres which in health would receive none of the exciting impulse. Between the lowest (automatic) functions of the cerebro-spinal nervous system and the highest (psychical) there is an ever-increasingly complex system of excito-motor processes, which may be in part or wholly under the pathological influence, whatever it be. Hence the *bizarre* character of the hysterical phenomena, and the circumstance that the symptoms always include modifications of those processes which underlie the mental faculties. The suspension of the power of control possessed by the higher centres explains the irregular movements, spasms, and convulsions. Hyperæsthesia and pain are dependent, probably, in hysteria, upon such a molecular change being initiated in the sensory ganglionic centres as is ordinarily propagated from the periphery. Hysterical paralysis, on the other hand, signifies that the power of the higher centres in liberating movements is in abeyance. In hysterical anaesthesia it is probably feeling or sensory perception and not the function of the sensory apparatus which is in abeyance, whilst the reflex actions which result from excitation of sensory nerves are performed in an orderly manner. A patient may work a needle with fingers which can be touched or pricked without the act being felt. Tactile impressions are conveyed to the ganglionic centres by the afferent nerves, and excite the action of efferent nerves so that the muscles are contracted. What is wanting is the participation of those higher centres in which consciousness runs parallel to this physiological action.

Ætiology.—Predisposing causes.—A state of more or less imperfect development of the higher nervous centres of congenital origin very frequently underlies it; it is probable, the various circumstances which apparently conduce to the hysterical conditions.

The female sex is much more prone than the

male to the affection, which usually occurs between the ages of fifteen and thirty, and most frequently of all between fifteen and twenty. Luxury, ill-directed education, and unhappy surroundings, celibacy where not of choice but enforced by circumstances, unfortunate marriages, alcoholism, premature cessation of ovulation, and long-continued trouble—all predispose to hysteria. A somewhat frequent antecedent is a long and wearisome nursing of a sick relation, with much broken rest. The disorder is only exceptionally found in women suffering from diseases of the genital organs, and its relation to uterine and ovarian disturbance is probably neither more nor less than that which obtains in other neuroses. Exception must be made in the case of prostitutes affected with venereal disorders, who are very prone to hysteria. In this class, however, the condition is complicated by the physical and moral influences to which their life subjects them, and amongst these alcohol frequently occupies a very important place. Like epilepsy, migraine, and some forms of insanity, hysteria is prone to be intensified at the catamenial period.

The occurrence of hysteria (although comparatively rare) in males is sufficient of itself to disprove the uterine theory of causation.

Determining causes.—These include painful impressions; long fasting; strong emotions; imitation; and shock to the nervous system, physical or moral.

SYMPTOMS AND DIAGNOSIS.—In the limited space in which it is necessary that the subject of hysteria should be treated, it will be best to describe together some of the most frequent forms which the neurosis takes, and the principles upon which a diagnosis can be made. Hysteria produces symptoms which may be referred to every function of the body. For consideration they may be roughly classed in the following groups, it being understood that all may occur either coincidently or in succession:—1. *Mental*. 2. *Sensory*. 3. *Motor*. 4. *Circulatory*. 5. *Visceral*.

1. *Mental*.—The intelligence may be apparently of good quality the patient evincing sometimes remarkable quickness of apprehension, but, carefully tested, it is found to be wanting in the essentials of the highest class of mental power. The memory may be good, but judgment is weak, and the ability to concentrate the attention for any length of time upon a subject is absent. So also regard for accuracy, and the energy necessary to ensure it in any work that is undertaken, are deficient. The emotions are excited with undue readiness, and when aroused are incapable of control. Tears are occasioned not only by pathetic ideas but by ridiculous subjects, and peals of laughter may inelegantly greet some trivial announcement. Or the converse may take place; the ordinary signs of emotion may be absent, and replaced by an attack of coma, convulsion, pain, or paralysis. Perhaps more constant than any other phenomena in hysteria is a pronounced desire for the sympathy and interest of others. This is evidently only one of the most characteristic qualities of femininity uncontrolled by the action of the higher nervous centres, which in a healthy state keep it in subjection. There is very frequently not only a deficient regard for

truthfulness, but a proneness to active deception and dishonesty. So common is this, that the various phases of hysteria are often assumed to be simple examples of voluntary simulation, and the title of disease refused to the condition. But it seems more reasonable to refer the symptom to impairment of the highly complex nervous processes which form the physiological side of the moral faculties.

2. *Sensory*.—Pain, hyperæsthesia, and anaesthesia occur with perhaps equal frequency. The diagnosis of the hysterical origin of such alterations of sensibility is effected partly by excluding the presence of other causes, and partly by consideration of any accompanying or antecedent peculiarities of manner and conduct. Hysterical pain, where it is associated with some evident local change, is found to be greatly in excess of that which would ordinarily accompany the observed cause. Where pain or hyperæsthesia is complained of in situations and of a character which would commonly point to some existing inflammation, it is necessary, by examination of the pulse and temperature, to exclude such a condition. Hysterical pain is apt to cease suddenly when the attention is diverted, and to be increased by inquiry and sympathy. Some of the most common seats of pain and tenderness are the following:—

(a) The lower part of the side of the chest (usually the left) simulating intercostal neuralgia, but distinguished from it by the tenderness being wide-spread, superficial, and not confined to certain points. Pressure here will sometimes occasion disturbances of respiration and circulation.

(b) Some of the vertebral spines, usually in the cervical and upper dorsal region. From the error of mistaking this for commencing disease of the vertebral columns of young women have been confined to a couch for months or years, and their health permanently damaged. The points of diagnosis are the patient's antecedents, there is often a history of aphonia, or paralysis, or hysterical fits. Or it may happen that, long after the pain has been first complained of, the patient has been seen to take a prodigious amount of exercise on some one occasion without complaint. A very much slighter pressure, too, causes pain than is at all usual in vertebral caries. It has to be remembered, however, that a patient affected with vertebral disease may also be hysterical.

(c) Acute pain in a joint, occurring usually some little time after a slight injury and giving rise to suspicion of inflammation, but distinguished from this by the fact that after a few days of great pain the joint does not feel hot to the touch, and is not swollen, and that the thermometer shows no rise of temperature. The pain is more easily excited, too, by touching the skin than by pressing the articulatory surfaces against each other.

It is necessary to remember that in locomotor ataxy there may be exquisite pains (of a shooting character) having their seat in a joint or its neighbourhood, and accompanied by some localized hyperæsthesia of the skin. The disease rarely affects young females, but it may do so, and the condition is then extremely liable to be

mistaken for hysteria. The chief points of diagnosis are, that in locomotor ataxy there will be—1. absence of patellar tendon reflex; 2. a peculiar character of the pains—lightning-like; 3. probably some analgesia of the extremities; and 4. an ataxic gait. See LOCOMOTOR ATAXY.

(d) Tenderness of the mamma or darting pains through its substance, recalling those of scirrhus. The absence of any lump, and the effect of engaging attention, will serve to distinguish.

(e) Pain in the head of very severe character, 'like a nail being driven into the skull' (*olacus*). This is probably neuralgic, and is by no means confined to the hysterical. There is also a more diffused pain, described as of great violence and exceedingly obstinate. This pain is sometimes suggestive of cerebral tumour, from which, however, it may often be distinguished by the fact that the ophthalmoscope shows no optic neuritis, and that there is no vomiting. But great caution is necessary in coming to a conclusion that severe and long-continued pain in the head is hysterical. And here it may be well to say that in an accurate knowledge of the characteristics of the disease supposed to be simulated lies the only safety as regards diagnosis. Nor must it be forgotten that persons with serious organic disease are frequently affected also with hysterical symptoms.

(f) Epigastric tenderness. Careful pressure will often show that the tenderness is at the origin of the recto-abdominalis muscles, and not in the stomach. But there is sometimes pain in the stomach itself, and this may be associated with disgust for food or depraved appetite.

(g) Tenderness in one or other iliac region, deep pressure upon which will sometimes evolve hysterical symptoms, and also in some cases of hysterical convulsions will check the paroxysm.

Anæsthesia may involve (though rarely) the whole body. It is more commonly confined to one half, and this the left, and is then frequently associated with tenderness in the iliac region of the same side; or it may be limited to a small patch. The sense of touch often remains whilst painful impressions and those of temperature cannot be perceived. The anæsthesia may be confined to the surface, or involve as well the deeper structures, into which pins may be stuck without evoking signs of pain. The left conjunctiva is often the seat of anæsthesia, so that it may be touched or even rubbed without any reflex movements of the eyelids being excited. So also the pharynx may be tickled without exciting the ordinary spasmodic contraction, and the epiglottis touched by the finger without inconvenience. Such affections of cutaneous sensibility may have to be looked for, as they are often unsuspected by the patient herself. As regards diagnosis the existence of peripheral nerve-lesions may be excluded, by the absence of trophic disturbances. The condition is not likely to be confounded with hemiplegia, unless perhaps when it has immediately followed a convulsive attack, and is accompanied by apparent loss of power in the limbs. Examination of the patient and her history will suffice for the diagnosis. The other special senses also may be disordered in hysteria. There may be intolerance of light, subjective sense of taste or smell, roaring noises

in the ears; or, conversely, loss of sight (either in half of both eyes, or in one eye), loss of smell, or taste, or hearing. Or there may be feelings as of a limb or other part being enormously enlarged, of the body being confined in a stiff case, of the feet being drawn up by strings under them, of 'pins and needles' around the waist, or of numbness and coldness in one half of the body (almost always the left). It may be said generally of the disorders of sensation that they are capricious in their appearance, coming and going, as they would not did they depend upon organic disease (this recurrence is especially significant); that they are very apt to ensue upon some moral shock or convulsive seizure; and that careful examination will prove them to be unaccompanied by such other symptoms as would be likely to be present did they depend upon the organic alteration which they simulate.

3 Motor.—The principal motor symptoms in hysteria are local spasm, more or less general convulsion, and paralysis. The most common of all symptoms of hysteria is the *globus hystericus*. A lump appears to the patient to arise from the epigastrium like an egg, and travelling upwards to the throat, causes a sensation of choking, and is often accompanied by an outburst of tears.

Spasm affecting some out of the various muscles concerned in the respiratory acts gives rise to a great variety of symptoms highly characteristic of hysteria. There may be cough of a peculiarly sharp, ringing character, constant except during sleep, unaccompanied by expectoration, strongly influenced by moral causes. A little observation will show that the cough does not occur when the patient is quite alone and apparently no one within earshot, but, on the other hand, it is greatly intensified by enquiry and solicitude. It ceases during sleep. Sometimes, instead of cough, a loud expiratory sound is produced, of most discordant character, resembling, perhaps, a railway whistle, the quacking of a duck, or the barking of a dog; and this may take place irregularly, or may be marked by a curiously distinct periodicity. Or there may be rapid, deep whooping inspirations, with signs of suffocation. Occasionally with the hysterical cough there is a hypersecretion of mucus; and if, as often happens, there is also disturbance of digestive functions and consequent tendency to emaciation, and at the same time such constriction of the air-passages as gives rise to sibilant rales, a *primæ facies* resemblance to phthisis is presented, which can only be distinguished by prolonged observation, aided by the stethoscope and thermometer. Laughing and crying are very frequent forms of expiratory spasm. Yawning, hicough, and sneezing are also met with. *Clonus* spasm of muscles, especially of those moving the head and shoulders, or back, is not uncommon. Or one of the muscles of the thigh may be so affected, and the apparent pulsation caused by the rhythmical contractions give rise to a suspicion of aneurism.

Tense spasm of one or more muscles of a limb is still more frequent. It is often very obstinate, and after enduring for months or years may suddenly resolve without any permanent alteration being left behind.

Contraction of a limb thus produced may continue during sleep and even resist the influence

of chloroform inhalation, unless this is pushed to its full extent. Should one of the abdominal muscles be thus affected, an abdominal tumour is produced, which may be mistaken for acme growth in the cavity; and if the pulsations of the aorta should be communicated to it, a strong *primæ facies* resemblance to abdominal aneurism is caused. The best mode of diagnosis is by faradisation, which, if persevered in for several minutes, will exhaust the muscular contractility and cure the ailment if it be of this kind. If it is not a 'phantom tumour' of this descriptior but a genuine growth, the muscle will be contracted by the current, and it may then be possible to feel the tumour as something evidently distinct from the muscle.

Convulsive seizures are of common occurrence, and are usually preceded by a sense of suffocation, difficulty of swallowing, pain in the belly or stomach, headache, vertigo, or some indescribable sensation in one of the extremities. There is often a cry as of one being choked, unlike the peculiar wailing shriek which ushers in the epileptic seizure. Usually there is not the extreme suddenness of attack which characterises epilepsy, but the patient may be manifestly struggling against the seizure for a small but appreciable interval. When at last she falls, she does not usually do so with violence enough to receive severe injury, and positions of danger are generally avoided. The epileptic often falls in the fir, the hysterical patient never. The spasms of muscles which succeed are often tetanic in character, and sometimes wear an aspect of design—the patient grips articles with her hands or teeth. The face may be more or less red. In epilepsy it is usually first pale and then livid.

There is often more or less complete opisthotonos, which is usually absent in epilepsy. It is doubtful how far consciousness is ever completely lost, but though for the most part it is retained during the attack, there are certainly cases in which it is to a great extent in abeyance. It is characteristic of hysteria that, however rapid and violent the contortions, the patient usually avoids inflicting any serious injury upon herself. During the attack gesticulations and language are apt to be used which may be reproachful, or marked by an amatory character as regards some bystander, such as is calculated to cause embarrassment. There may be a single convulsive seizure, terminated by a fit of weeping and the passage of a large quantity of almost colourless urine of low specific gravity. Or there may be a succession of attacks extending sometimes over several hours. The tongue is not bitten. As a rule the hysterical patient rapidly returns to her ordinary condition after the outburst is completed, and fails to show the heaviness and tendency to sleep which is characteristic of epilepsy. The variety seen in the character of hysterical convulsions suggests that the pathological influence involves the nervous centres, sometimes more and sometimes less extensively; showing every degree of muscular movements, from those of a highly co-ordinated or quasi-voluntary kind, down to those of a simply tetanic form, such as appear to indicate either that control of the reflex function of the spinal cord is temporarily suspended, or that the cerebellar influence, as Hughlings

Jackson thinks, is being allowed to have full play, owing to some peculiar condition of the cerebrum interfering for a time with its normal power of antagonism. But it must be borne in mind that the hysterical patient may, like others, become epileptic, and that there is nothing to prevent the chronic epileptic betraying occasionally symptoms of hysteria. Such mixed cases are often difficult of diagnosis, and it is usually only a prolonged observation which succeeds in distinguishing the nature of the condition. Movements which somewhat resemble those of chorea are occasionally met with, but their character and the surrounding circumstances usually make it easy to distinguish them.

Paralysis may affect any of the limbs in hysteria, but paraplegia is the more usual form. Hemiplegia is comparatively rare. The muscles retain their nutrition. There is often at first a slight loss of irritability to induced currents, but after a very few applications this becomes normal. At first, too, considerable electro-cutaneous and electro-muscular insensibility may be present. If the form of paralysis be hemiplegic, the mouth is not affected; if paraplegic, the sphincters are not paralysed, and there is never any bedsores. If the arm be the limb affected, and the examiner, after flexing it slightly leaves go, it will sometimes remain in the flexed position, which it would not do in hemiplegia. It is noteworthy that in half the cases of hysterical paralysis, there is no history of antecedent convulsions. (Itaneous anaesthesia of the extremities will give rise sometimes to a pseudo-paralysis, and muscular anaesthesia may cause symptoms of ataxy. These may be distinguished from the result of organic change by careful examination. Hysterical speechlessness may be distinguished from aphasia by the patient being able to write down with great facility the wishes she is unable to express in speech; and from localised paralysis of the tongue, by her being perfectly able to swallow.

4. *Circulatory*.—There may be syncope which will simulate dying. After an indescribable sensation at the heart—a fullness or stifling feeling—the pulse becomes almost imperceptible, the patient is speechless, and, for periods varying in length, is apparently in a most precarious condition, recovery taking place after prolonged sighing. Or there may be tumultuous action of the heart. The abdominal aorta (and sometimes also other arteries) is occasionally the seat of powerful pulsations, which are visible in their effects upon the abdominal wall and strongly suggest the existence of aneurysm. The capillary circulation may be deranged in the two directions of hyperemia and ischaemia. In the former there is a patch of redness of the skin accompanied by a feeling of burning and tenderness, in the latter, which is especially seen in conjunction with anaesthesia, the skin is pale and no bleeding follows the pricks of a pin. In a recorded case, pressure upon a tender spinous process checked the radial pulse for a time.

5. *Vomiting*.—Vomiting is sometimes a very obstinate symptom, all food taken being speedily ejected, the condition lasting a surprisingly long time, often for many months, without usually so much prostration as might be expected, but nevertheless with great loss of weight. Or there may

be such an active aversion from food as renders it very difficult to support nutrition; or a depraved appetite may cause substances to be swallowed which have no nutritious property. In the belly there is frequently a hyper-secretion of gas with spasm of the bowels, causing borborygmi and noisy eructations. Intestinal gas may be imprisoned between two points of spasmodic contraction of the intestine, giving origin to a tumour capable of being moved about in the abdominal cavity, and of sudden resolution. These balloons, it is probable, are sometimes mistaken for tumours of the spleen, kidney, or other organ. It is not uncommon to have retention of urine, the bladder becoming greatly distended, but contracting at once and expelling its contents if the patient be placed in a hip-bath, and a bucket of cold water be thrown over the pelvis. In other cases there is an unduly frequent desire to empty the bladder. The secretion of urine may be suppressed almost entirely (but this is very rare), the little urine that is passed containing an unusual proportion of urea, which is also found in the vomiting accompanying this condition.

There is sometimes very obstinate constipation, giving rise to enormous impaction of faeces—occasionally also diarrhoea.

Cases occur in which the symptoms of cerebro-spinal sclerosis of the disseminated form, after persisting perhaps for many months in a young woman, rapidly or even suddenly disappear. The close resemblance to a disease which is not only incurable but tends to become progressively worse, is so strong that it is often impossible to form a diagnosis, and a very guarded prognosis becomes necessary. In the present state of our knowledge it is customary to class such cases with those of hysterical paralysis; but it is quite a question whether they are not really cases of incipient cerebro-spinal sclerosis, recovering ere the stage of irreparable change is arrived at. There is good reason to think that cases of disseminated cerebro-spinal sclerosis are not at all unfrequently supposed to be simple examples of hysteria. The disease is characterised in its early stage (the only period when mistake is possible) by some general weakness of limbs, accompanied by slight tremors on voluntary movement only, and an utterance which is slow and drawing, with occasional slurring of words. Careful examination, especially noting the circumstance that, for example, the arm only shakes when the patient is directed to take hold of an object, is usually sufficient to distinguish the disease from hysteria, but there is sometimes considerable difficulty, and caution should be observed in avoiding hasty conclusions.

Sequelae.—Hysterical symptoms sometimes pass into those of mania, melancholia, and occasionally also of dementia.

Prognosis.—This is favourable as regards life, death from hysteria being very rare. Recovery for a time is common enough, but too often there is a return of the disease, the symptoms being usually of a different kind. Some patients will run through almost every conceivable phase of the disorder in turn. As a rule there is a tendency to cessation of the disease after the climacteric period. It occasionally happens, however,

that the disease is continued into an advanced period of life.

TREATMENT.—If Medicine were in a position to regulate the mode of life, food, education, and especially the selections for propagation of the species, it is probable that in succeeding generations hysteria would become more and more rare in the race. It can do, however, but little for the individual. Intercurrent maladies must of course receive the treatment proper to them. Where anaemia is present much good may often be done by iron. States of malnutrition tend to precipitate and intensify hysterical symptoms; and to remedy these is often to do much for the concomitant nervous disorder.

But probably the greatest amount of benefit which can be brought to bear upon the hysterical patient is through her surroundings. A girl who has not spoken above a whisper for months whilst at home, will often recover her natural tone of voice in a week if placed under the judicious discipline of strangers. This is a well-known circumstance, and the fact has tended very much to the belief that hysteria is simply vicious simulation. Such an inference is unjust.

That an altered relation of the ganglionic nerve-cells to the blood-supply forms at least a part of the pathology of hysteria appears probable from the effects of fasting in provoking hysterical outbursts, and the influence of food and stimulants in postponing them. Ammonia inhaled by the nostrils is a well-known and valuable agent for the purpose. Alcohol should be avoided altogether, as there is great danger of excess.

It is through the sensory nerves that the most rapid influence is brought to bear upon the hysterical condition. Thus cutaneous anaesthesia and hyperaesthesia may often be rapidly cured by the application of strong induced currents to the portion of skin, aphonia by acting in a similar way upon the skin covering the larynx. Paralysis of the limbs is in many cases quickly cured by the same means.

Hysterical convulsions may almost always be cut short by douching the patient very freely indeed with cold water. This should be poured from a height upon the face. For a few seconds there is no perceptible effect, then the breathing becomes gasping, and the patient seeks by moving away to avoid any further application. It often happens that the remembrance of this treatment serves to prevent a repetition of convulsions, but it would be wrong to conclude from this that the proceedings of the patient had been voluntary. The effect of the cold douche is to create, through the medium of the cutaneous nerves, a sudden change in the character of the blood-circulation, which may well influence the state of the ganglionic nerve-centres. The supposition seems fair that to remember the shock is to have a weak excitement of the nerve-centres which were strongly excited by the application.

Bromide of potassium, which is of such value in the *grand mal* of epilepsy, has no influence in preventing hysterical convulsions. In a doubtful case the exhibition of this drug is therefore useful for purposes of diagnosis. Valerian (the powder or tincture) has an unquestionable effect in the convulsive and spasmodic symptoms of hysteria, little or none probably upon the para-

lytic phases. Assafoetida by enema is useful in tympanites and colic of hysterical origin. Small doses of strychnia and opium are useful in relieving some of the distressing feelings complained of by hysterical patients.

It is often a question whether the hysterical should marry. Where the disorder is slight and the general health is good, marriage may be advised, supposing that the prospects of a happy union are favourable. But in very severe cases, and especially when there is also a strong neurotic history in the family, it should be discountenanced. Nothing but harm can be expected from the strain of domestic cares upon a congenitally defective nervous system. T. BUKHARD.

HYSTERICAL INSANITY.—Almost every variety of insanity may present in certain patients features which are commonly known and termed 'hysterical.' Melancholic individuals will be afflicted with hysterical paraplegia or other paralyses. Some will become cataplectic or apparently unconscious, others will display all the phenomena of hystero-epilepsy. Not unfrequently do we see a violent outburst of acute mania culminating and subsiding in a brief period of time, resembling in this an ordinary attack of 'hysterics.' It may be doubtful, however, whether hysterical insanity should be looked upon as a special variety of the malady. It seems more correct to look upon it as insanity occurring in hysterical patients, and characterised by the phenomena peculiar to them. We may expect sudden changes of symptoms, sudden improvements, and sudden relapses.

PROGNOSIS.—The prognosis is unfavourable, as this insanity is found in patients of an unstable nervous organization, prone to frequent derangement. Even if recovery takes place, subsequent attacks are not unlikely to occur.

TREATMENT.—Such persons require above all others moral treatment. Medical treatment should be directed towards the improvement of the general health rather than the removal of special symptoms. G. F. BLANDFORD.

HYSTERITIS (*barépa*, the womb).—Inflammation of the womb. See WOMEN, DISEASES OF.

HYSTERO-EPILEPSY.—**SYNON.** : Fr. *Hystéro-Epilepsie*; *Hystérie épileptiforme*, Ger. *Hysteroepilepsie*.

DEFINITION.—A term applied to a form of hysteria of unusual gravity, the convulsions in their violence recalling those of epilepsy, and characterised by the occurrence of remarkable forms of anaesthesia, paralysis, and contraction of muscles.

ÆTIOLOGY.—The condition is one which must be classed with hysteria, and not with epilepsy, and the circumstances which tend to the production of the former disease are here equally potent. See Hysteria.

SYMPTOMS AND DIAGNOSIS.—It is to the French school, and especially to Professor Chareot of Paris, that we owe the most important descriptions of this disease, which would appear to be more common on the Continent than in England. The symptoms may be divided into:—1. *Motor*; and 2. *Sensory*.

1. *Motor.*—Convulsive seizures occur, preceded

by an hysterical aura (abdominal or epigastric), which usually gives the patient timely warning enough to enable her to place herself in a position of safety. Then there is a shriek, the face is pallid, and she falls (perhaps whilst endeavouring to quit the room), the features become distorted, and the limbs pass into a state of tonic rigidity. There is foaming at the mouth, sometimes the tongue is bitten, and there may be some clonic convulsions with lividity of features. Relaxation of the muscles and a more or less comatose condition succeed, to be followed shortly, however, by contortions and gesticulations of a violent character, coarsely suggestive of the influence of various passions—wrath, fear, disgust, lust. Or there may be meaningless writhings, presenting a hideous aspect. To this phase sometimes succeeds hallucination of vision, or of hearing. Hats and serpents and other objects of horror are seen. The attack ends with sobs or hysterical laughter. There may remain a temporary inability to empty the bladder or to swallow food.

Convulsive seizures of this co-ordinated or purposive character, although much more common in the female than the male sex, are by no means confined to the former. The condition is not unfrequently observed in boys, less often in men. In the latter there is usually the history of some great moral shock antecedent to the first outbreak.

In patients liable to attacks such as have been described, it is not uncommon to find a *contracture* of one or more limbs. This may assume the *hemiplegic* or *paraplegic* form; and it may be of a passing character, lasting a few days only, or enduring for many years. The attitude may be either that of rigid flexion or extension; and it is found to remain during sleep, only relaxing under the profound effect of chloroform narcosis. The limb so affected does not suffer in its nutrition, and the reaction of the muscles to electrical currents remains normal.

The contractures, as well as the sensory disturbances described below, may be said to be practically confined to patients of the female sex. It is very rare indeed to find them in males.

2. *Sensory*.—It has been noted that in female patients thus affected (as indeed is common in hysteria generally) there is apt to be a pain in one or other iliac region, most often the left.

—Which is sometimes constant, and in other cases is only discovered by pressure. The seat of this pain is thought to be the ovary, and it is found that whilst a moderate pressure in this region may determine the production of the aura and sometimes of an hysterical attack, energetic compression at the spot will very often cut short the convulsive seizure.

Anæsthesia and *analgesia* are apt to be found sometimes in both sides, but much more frequently in one half of the patient's body, parted off from the other by the median line, and thus involving apparently half the head, face, and trunk, as well as the upper and lower extremities, though it may be in different degrees of intensity. It not seldom happens that the patient is herself unaware of the existence of this insensibility until examination has disclosed it. The loss of sensibility sometimes affects also the special senses; and smell, taste, hearing, sight,

and the perception of colour, may each or all be lost on one side.

Accompanying the *analgesia* it is often seen that the pin-prick employed to test the condition fails to draw blood on the affected side, whilst readily doing so in the opposite limb.

Where there is loss of power of the limbs with contracture and *anæsthesia* following a convulsive seizure, it is not difficult for the condition to be ascribed to an attack of hemiplegia, resulting from organic disease, and there is sometimes a doubt on this matter which is not easily resolved. The points of most value in making a differential diagnosis are the following:—a. The absence from the first of any deviation of the tongue or facial paralysis. After a time, no doubt, in some cases of hemiplegia of organic origin these symptoms become scarcely visible, but it may be said that practically at the onset they are always present to a greater or less extent. b. The extent and completeness of the *analgesia*, especially the mode in which it affects the trunk, which ordinarily escapes in hemiplegia. Such complete *anæsthesia* as occurs in these cases is rarely observed in hemiplegia of cerebral origin. In spinal hemiplegia, again, it would occupy, as Brown-Séquard has pointed out, the side of the body *opposite* to that affected with motor paralysis. Besides these there is rarely much difficulty in finding in the symptoms, surroundings, or history of the patient, circumstances which, combined with those described, throw a strong light on the nature of the condition. The hysterical patient may present, for example, retention of urine, ovarian tenderness, and tympanites; and in her history there may be an account of aphonia, convulsive seizures occurring under emotion, hysterical cough, or some other feature which tends to stamp the case as one belonging to this great neurosis.

Occasionally these contractures remain permanent. Much more frequently they relax, after a longer or shorter period, and the relaxation almost always takes place suddenly, usually under the influence of some moral shock.

It will sometimes happen that paresis and contracture of a limb will occur without any previous history of hysterical symptoms, and the possibility of this must always be borne in mind. Where there is during many hours a long-continued succession of fits with brief intervals of immunity, considerable doubt may arise as to the nature of the attacks, because a very similar, numerous, and rapid recurrence of fits sometimes takes place in true epilepsy. We are indebted to Charcot for the observation that whilst in the case of the epileptic seizures of this kind the temperature is observed to rise greatly (attaining, for instance, a height of 105° F.), no such great increase is noted when the fits are of hysterical origin—a slight elevation only occurring.

In cases of hystero-epilepsy it has been noted that there is often colour-blindness, affecting the eye on the same side as the hemianæsthesia—the order of disappearance, in most cases, being the following:—violet, green, red, orange, yellow, blue. Violet is the colour most easily lost, red and blue, according to Charcot, being those which persist most, except in those cases where achromatopsia is absolute, that is where the patient

looking at a painting sees nothing but black and white.

Remarkable results have been known to follow the application of metallic plates and the approach of a powerful magnet to the anæsthetic side of the body. It is found that if a small plate of some metal be applied for a few minutes to the skin, a return of sensibility occurs, touches and pricks previously unperceived are felt, and colour-vision is restored in the affected eye. The particular metal which will effect this change has to be sought by experiment: in one person gold, in another silver, in others again iron, tin, or copper, alone producing the effect. So again it is stated that the approach (without actual contact) of a powerful horse-shoe magnet will produce a similar effect to the contact of a metal. In either case, *pari passum* with the return of sensibility on the affected side, it is noted that the other half of the body acquires the anæsthetic state. There is a transference apparently of the phenomena. The approach of a magnet, it is also found, will cause a contracture to relax, the relaxation lasting for many hours. But in this case, again, the corresponding limb of the previously normal side is found to present evidence of paresis. In two instances Rosenthal and the writer have found defective electrical excitability, as tested by sudden interruption of a strong voltaic current, in the cerebral hemisphere opposite to the side

which is marked by anæsthetic symptoms. In the writer's own case the experiment was followed by considerable improvement in the cutaneous sensibility.

TREATMENT.—Cases of hystero-epilepsy are not amenable to any treatment by drugs. Powerful moral impressions, especially energy and commanding influence in the medical attendant, are more potent than anything else in bringing about recovery, but it is not always that these can be brought to bear. It is desirable, therefore, that in suitable cases the influence of the measures just described should be tested. In cases of convulsion strong pressure should be made upon that cranial region in which tenderness is discovered. In examples of contracture and hæmianæsthesia an application of metallic plates of various kinds may well be made to the skin of the affected side.

Very useful effects are often produced by the application of strong Faradic currents, which may require to be persisted in ere any influence is produced. Blisters also repeated every three or four days are occasionally very useful in causing the relaxation of a contracted limb and the return of sensibility to an anæsthetic skin.

Removal of the patient from the family circle and the society of frightened or sympathising friends, is in most cases a *sine qua non* of successful treatment.

T. RUXFORD.

ICE, Therapeutics of. See **COLD**, Therapeutics of.

ICHORRHÆMIA (*ixôp*, puriform matter, and *aima*, the blood).—A morbid condition of the blood, caused by the absorption of septic materials. See **PYÆMIA**; and **SEPTICÆMIA**.

ICHTHYOSIS (*ixôv*, a fish).—**SYNON.**: Fish-skin disease; Fr. *Ichthyose*; Ger. *Fischschuppenausschlag*.

DEFINITION.—An affection of the skin which has received its name from the breaking up of the cuticle into polygonal areas, which suggest the idea of the scales of the fish. The surface of the skin is dry, rigid, rough, and greyish in colour; and the cuticle exfoliates in fragments, which in one place resemble dust, and in others are composed of thin glistening laminae, like those of mica or bran.

ÆTIOLOGY.—As a defect of development and normal growth of the skin, ichthyosis is a congenital affection, and often hereditary; and the degree of its manifestation will depend on accidental circumstances of various kinds, and more particularly on such as appertain to food and cleanliness.

• **ANATOMICAL CHARACTER.**—In ichthyosis the cuticle is more abundant than natural; the

fibrous tissue of the derma is condensed and hard, the papillæ cutis are enlarged and elongated, the subcutaneous connective tissue is lax and fatless, and the whole organ is devoid of succulence and elasticity. In a word, it may be said to be starved. The remaining characteristics of the disease are such as might be predicted from this description. The cuticle formed in excess is hard and brittle, and breaks up into fragments corresponding with the areas of the lines of motion and wrinkles of the skin, the fragments being simply pulverulent in one part, as upon the inner side of the limbs, the neck, and front of the trunk; angular and prominent in the neighbourhood of the joints; and smooth, flat, and polyhedral on the inter-nodular parts of the limbs. The follicles of the skin are filled with dry exuvie and dry sebaceous substance, which in some situations quarts on the surface, thereby increasing the thickness of the epidermic crust. The skin as a whole is marked with coarse wrinkles, resulting from the stiffness and hardness of its substance; and from the looseness of the subcutaneous tissue it moves freely on the fascia beneath. While the general character of the integument is that of want of harmony as to growth with the rest of the body of the individual, there is a defect

of the oily secretion of the skin, sometimes also of its aqueous secretion; a want of the clearness, transparency, and lustre which are met with in the healthy skin; and an exhalation of an unpleasant odour.

VARIETIES.—The most striking modifications of ichthyosis are to be looked for on the limbs, where the disease is most marked, and the scales of greatest magnitude, on the hands and feet, which are dry and horny and deeply wrinkled; on the neck and trunk, where the exfoliation is pulverulent; and upon the face, where the cuticle is shining, roughened by the edges of exfoliating laminae, and seemingly distended, altering the complexion to a brick or apple-red. Another modification results from the presence of an excess of sebaceous substance, which, by its adhesion to the skin, produces prominent scales—*Ichthyosis sebacea*—varying in thickness in different parts of the body, and sometimes giving rise to spines of considerable length and thickness—*Ichthyosis spinosa*.

These modifications occasion a certain diversity of appearance in the affection, which has suggested a variety of synonyms. Thus, when its conspicuous symptom is dryness of the skin, we have termed it *Xeroderma*. When the network of lines which bounds its scales has attracted especial attention it has been named *Ichthyosis reticulata*. When the mother-of-pearl-like polish of the smooth area within the meshes of the lines of motion has been conspicuous it has been called *Ichthyosis nuda* and *Ichthyosis nacræa*. When the concretion of the epidermic and sebaceous substance assumes the figure of the scales of reptiles, the term *serpentina* is applicable, and *Ichthyosis serpentina*; whilst the elongated form of crust has given origin to the term *Ichthyosis hystrix*, the 'porcupine disease.'

TREATMENT.—These considerations lead us to the principles of treatment of ichthyosis, and suggest as primary indications:—*first*, to promote an improved nutrition of the body; *secondly*, to effect the removal of the excess of epidermic matter and scales; and, *thirdly*, to stimulate the innervation and circulation of the skin by innunction and friction. The first of these indications is to be achieved by the use of nutritious food, cod-liver oil, arsenic, iron, and tonics in general; the second, by suppuraceous ablations and frictions, and especially by the Turkish bath and shampooing; and the third, by frictions of oily and gently stimulating liniments into the skin; one of the most suitable of these remedies for the purpose being the oleum theobromæ, or cocoa butter.

ERASMUS WILSON.

IOTERUS (*levis*, a weasel; with yellow eyes).
A synonym for jaundice. See JAUNDICE.

IOTUS SOLIS (*ictus*, a stroke; *sol*, the sun).
A synonym for sunstroke. See SUNSTROKE.

IDIOCY (*Idiocy*, a person private or apart).
SYNON.: Feeble-mindedness; Fr. *Dimence simple*; *Idiotisme*; Ger. *Die Sprachengeheit*; *Blödsinn*.

DEFINITION.—Mental deficiency occurring during infancy or the early periods of life.

The term *idicy* is not a scientific one, but it is convenient to employ it here to include a class of maladies which differ essentially from insanity

both as to their nature and treatment. The strict meaning of an idiot is, 'a solitary one,' but it has become so much used as a term of opprobrium that it were well if the phrase, 'feeble-minded,' could take its place.

DESCRIPTION.—The term *idicy* covers such a large area, and includes such a great variety of cases, that there is endless gradation in its manifestations, from slight departure from a normal condition, to that state of profound idicy in which the unfortunate subject thereof sees nothing, feels nothing, does nothing, and knows nothing. The typical illustration, however, is best conveyed by reference to an average condition. For the most part, the lesion is not only a psychical one, but profoundly affects the physical, and frequently the moral life. The stature is less than normal, with great tendency to assume a stooping posture. The skin is often coarse, deficient in elasticity, and lax, with increased development of areolar tissue. The muscles are weak and flabby, and respond feebly and irregularly to the action of the will. The bones are often yielding and deformed. The circulatory system is usually weak, rendering the patient liable to destructive chilblains and frostbite, inducing perilous effects from exposure to a low temperature, and rendering slow any reparative process. The lungs are extremely liable to inflammatory attacks, both in their bronchial tubes and parenchyma, and prone to tubercular disease if the subject be resident on a clay soil. The digestive system is liable to be deranged by defective mastication of food, and alternately subject on the one hand to constipation from defective innervation, and on the other hand to diarrhoea from catarrh, resulting from rapid alternations of temperature. The sexual functions are often abnormal; there is a tendency to masturbation very early in life, while puberty itself is generally delayed, and often sterility exists. There is not unfrequently phimosis and undescended testis in the male, and non-development of the ovary in the female. The motor functions are abnormal; there is usually defective co-ordination, resulting in a deficiency in purposive acts, while there is a tendency to the production of purely rhythmical and automatic movements. There is diminished sensibility, so that what is painful to others is borne with complacency. Speech is defective, partly from want of co-ordination of the muscles of the tongue, partly owing to deformations of the mouth and palate, and partly to inability to convert ideas into words. The sight is often defective, due to hypermetropia, to imperfect retinal sensibility, to congenital cataract, or to diminished accommodation. These conditions are frequently associated with strabismus or nystagmus. The sense of smell is lessened, and the discrimination of odours almost nil. The sense of taste is defective, leading to the eating of things of an unpalatable, and even repugnant nature. The faculty of hearing is not much interfered with, except in cases where there has been destructive disease of the ear. The faculties of observation and attention are limited. There is generally great fondness for music, and simple airs are often readily learned. The memory is not usually very defective, and there are often instances of remarkable power in this respect. There is very little imagination,

power of abstract thought, while judgment and reasoning power are almost entirely absent.

Classification.—The best classification of idiocy, the one which most assists in the prognosis and treatment, is that which is based on its etiology. The whole of the cases may be divided into three important groups, which groups afterwards admit of subdivision. The primary groups are:—1. *Congenital*; 2. *Developmental*; and, 3. *Accidental*.

1. *Congenital idiocy*.—The congenital group includes all those cases which at the period of birth manifest signs of defective mental power, associated usually with conditions of the head, skin, and other organs, which are indicative of a congenital origin. They are cases which have never possessed ordinary mental power. The congenital group contains the following subdivisions:—*a*. Strumous; *b*. Microcephalic; *c*. Macrocephalic; *d*. Hydrocephalic; *e*. Eclampsic; *f*. Epileptic; *g*. Paralytic; and *h*. Choreic.

2. *Developmental idiocy*.—The developmental group includes a smaller number of cases, where the child is born manifesting an average intelligence through infancy, or even up to the commencement of puberty, but from causes which have influenced the nutrition of the embryo during its intra-uterine life, is born with a proclivity to mental break-down during one of the developmental crises, the crises being the periods of the first dentition, of the second dentition, and of puberty. The group includes those cases in which speech and mental faculties are lost in children in whom previously the intelligence was good—cases where the brain and nervous power was sufficient for its early years, but insufficient to carry it through evolutionary stages. They usually present outward signs in their cranium or elsewhere that the tendency to catastrophe was born with them. The developmental group embraces the following subdivisions:—*a*. Eclampsic; *b*. Epileptic; and *c*. Choreic.

3. *Accidental idiocy*.—The accidental group includes all those cases of idiocy where the child has been born with a normal nervous system, free from any present or potential defect, when unfortunately a fall, a fright, epilepsy, the result of some peripheral irritation, disease of the bones of the ear sequential to measles or scarlet fever, meningitis, or other cause, may lead before puberty to mental break-down—a break-down not of a genetic, but of a purely accidental origin. (For the group of idiots produced by endemic influence see **Cretinism**.) The accidental group includes:—*a*. Traumatic; *b*. Inflammatory; and *c*. Epileptic idiocy.

Ætiology.—The production of idiocy is multifiform in its causation; often more than one factor has been at work. The *congenital* kinds are produced by neuroses, struma, tuberculosis, alcoholism, over-intellectual work, over-sexual indulgence, and constitutional debility of the progenitors. Syphilis holds but a very unimportant place. Intermarriage of relations, where there is a constitutional taint, in consequence of its insuring the existence of two potent factors; fright and emotional disturbance, or anxiety of any kind on the part of the mother during her pregnancy; and prolonged parturition and suspended animation at birth, are also to be reckoned

as causes of congenital idiocy. The *developmental* kinds have their proclivity given to them by causes affecting their nutritive life *in utero*, notably emotional disturbances, and sickness produced by the pregnancy or a prolonged sequestration. The exciting cause is a developmental crisis, such as occurs at the periods of dentition, and the evolution of puberty. Masturbation is a most important factor in determining this kind of idiocy. The *accidental* kinds are produced by injuries to the cranium of any kind, sunstroke, exanthematous disease, tubercular or other forms of meningitis, inanition, epilepsy referable to worms, masturbation, or other sources of peripheral irritation.

Prognosis.—In idiocy the future of the patient will be forecast by reference to the nature of the case. Other things being equal, patients paralytic or epileptic are less amenable to treatment than others, but the worst results are obtained among cases of accidental origin. It is important to recognise the fact that congenital cases, with marked traces of their infirmity in their faces and bodies, are, for the most part, more susceptible of improvement than the developmental, and these again than the accidental, who may have no appearance of idiocy in their faces or bodies; that, in fact, the prognosis is often inversely as the patient is winsome, fair to look upon, and comely.

Treatment.—The treatment of idiocy consists of a judicious combination of medical, physical, moral, and intellectual agencies. The patient should be rescued from his *solitary* life, and have the companionship of his peers. He should be surrounded by influences, both of Art and Nature, calculated to make his life joyous, to arouse his observation, and to quicken his power of thought. The basis of all treatment should be *medical* in an enlarged sense. Success can only be obtained by keeping the patient in the highest possible health. The dietary should be liberal, containing a fair proportion of nitrogenous elements, while rich also in phosphatic and oleaginous constituents. The food should be presented, too, in a form suited to the masticatory power of the patient. It is of importance that the rooms should be well-ventilated, whilst kept warm; and daily baths with shampooing should be employed. Of first importance is the soil: a clay soil is fatal to all proper progress, inducing tuberculosis, and lowering the vital power. *Physical* training forms an important part of treatment. The attenuated muscles have to be nourished by calling into exercise their functions, and the automatic and rhythmic movements have to be replaced by others which are the product of the will. The simplest movements should be first taught, then the more complex, thus causing to grow up together the mandate and the result. From purposeless acts the idiot thus builds up a series of co-ordinated and voluntary movements which are applicable to the wants of daily life. The training has to be carried out in minute detail, so that every voluntary muscle and every congeries of muscles may be called into action, and trained to fulfil with rapidity the end for which they are designed. The *moral* education is of paramount importance. The pupil has to be taught to subordinate his will to that of an

other. He has to learn obedience, that right doing is productive of pleasure, and that wrongdoing is followed by deprivation thereof. Corporal punishment should be forbidden; the affective faculties of the patient should be cultivated, that the deprival of the love of his teacher should be felt as the greatest punishment, and the manifestation of it his highest reward. In no case should the punishment interfere with hygienic treatment. The intellectual training must be based on a cultivation of the senses. The patient should be taught the qualities, form, and relation of objects by their sense of touch; to apprehend colour, size, number, shape, and relation by sight; to understand the varieties of sound when addressed to the ear; the qualities of objects by the taste and smell. These lessons should be of the simplest at first, and gradually cumulative. Nothing should be left to the imagination. The idiot must be taught the concrete, not the abstract. It is in this way we should give him the basis from which the reasoning and reflective faculties can be built up. Synchronously with this, use should be made of the physical powers which have been cultivated. He should be taught to dress and undress himself, to acquire habits of order and neatness, to use the spoon or knife and fork, to walk with precision, to handle with tact. The defective speech is best overcome by a well-arranged plan of tongue-gymnastics, followed by a cultivation of the purely imitative powers. J. LANGDON DOWNS.

IDIOPATHIC (*Idios*, peculiar, and *pathos*, a disease).—A term applied to a morbid condition when it arises primarily, and not in consequence of some other disease or injury. It is used in contradistinction to *symptomatic* and *traumatic*.

IDIOSYNCRASY (*Idios*, peculiar; *syn*, with, and *krasis*, constitution or temperament).

DEFINITION.—This term, like many others used in science, has a more restricted application than its etymology would indicate. From meaning the personal constitution of an individual, it has come to mean any peculiar and not obviously correlated reactions against external influences exhibited by any individual. It is not to be confounded with 'constitution,' which is the foundation of the individual, his powers, capacities, and organisation; nor with 'temperament,' which denotes the correlation of powers and tendencies with the physical conformation of the individual, which has therefore a generic or race application, and which is defined by some writers as the 'general form' of the man. Commonly, any single peculiarity of a person is spoken of as 'an idiosyncrasy,' so that one individual may, in this sense of the word, manifest several idiosyncrasies or personal attributes.

DESCRIPTION.—Idiosyncrasies, so defined, may be mental or physical; may be innate or acquired; may be permanent or temporary.

The existence of idiosyncrasies being declared chiefly through the agency of nerves, and their operations being mostly capable of being brought under laws of innervation, Prochaska, Claude Bernard, and other authorities have regarded them as 'a peculiar affection of the nervous system.' But a review of the phenomena admitted to belong to the class will be found to

compel us to recognise in many cases a more comprehensive relation, involving the whole organism, or parts of it other than the nervous system.

In the enumeration of the principal kinds of idiosyncrasies, to purely mental manifestations of likes and dislikes toward persons, things, and pursuits,—affections covered by such terms as 'sympathy,' 'antipathy,' 'predilection,' etc.—must be added reactions in which the mind, the emotions, and the organic nervous system are affected simultaneously, but in varying proportions, by impressions received through organs of sense.

For example, vision may be the channel of affection. Syncope is produced in some persons by the sight of blood; or, as is related by Prochaska, swooning may invariably occur on the sight of beetroot. As regards olfaction, some people are distressfully affected, in both bodily and mental ways, by the exhalations from certain animals, the cat in particular; in others, horror and fainting are induced by the odour of roses or of apples. And so on through the rest of the senses.

In another group of idiosyncrasies the higher nervous centres play no part, the phenomena being of reflex production through the spinal centres, or being due to direct poisoning of the system or of organs. Among foods or drugs swallowed, among gases or dusts inhaled, among substances brought into contact with the skin, many, harmless to the majority of men, are for this or that individual irritants or poisons. For instance, eggs, honey, sugar, or fish may produce gastric pain, nausea, or vomiting; strawberries are to a few persons a most deadly poison, producing symptoms of intense nervous shock; convulsive spasms may be excited by the smell of musk or civet; asthma by the inhalation of the powder of ipecacuanha; urticaria by the eating of shell-fish, or even by the application of the yolk of egg to the skin.

Some men there are love not a gaping pig;
Some that are mad if they behold a cat;
And others, when the bag-pipe sings i' th' nose,
Cannot contain their urine.

Merchant of Venice.

Idiosyncrasies confronting the use of drugs have a special interest for the medical man. They may be of a qualitative nature, as in the production of unusual symptoms with dangerous or fatal results by anesthetics, or in iodism; or of a quantitative nature, as in the case of opium and belladonna, minute doses of which will poison some persons, while doses of them, large enough to destroy a dozen average individuals, may be taken by one here and there with impunity.

The consideration of this part of our subject introduces the question of the variations of idiosyncrasies. The transient oddities of susceptibility arising in pregnancy, hysteria, and madness, are excluded by some authors from the category, but as they only differ in their transitory character from other idiosyncrasies, we shall here associate them with those modifications of reactive sensibility to which the term is commonly extended. Seeing that the causes of innate idiosyncrasies are for the most part unexplained, we may search out in varying or acquired idio-

sympoms varying correlations which may help us to the ultimate better understanding of the former group. Thus we know that intolerance of opium may arise in some morbid states the nature of which is fairly known; that tolerance of, or comparative indifference to, the same drug may be attained by its constant use. As in pregnancy new idiosyncrasies appear, so age, habits, and state of body may each and all modify the reaction of any individual towards his surroundings; may change his behaviour under the influence of drugs; may at one time charm him against morbid poisons, at another time leave him their easy victim; may make him inflame sometimes in a suppurative, sometimes in a plastic way. From this point of view, we may with Claude Bernard summarise idiosyncrasies as being 'mere manifestations of the ordinary laws of physiology.'

Imaginary idiosyncrasies.—Persons are not unfrequently met with who, held by prejudice, or misled by fancies or unsound judgments, declare that particular foods and medicines disagree with them. It may often be found, on investigation, that the assertion is incorrect. The obstacles offered to effective treatment by such fancies are sometimes of grave importance, tacking severely the sagacity of the medical man in the way of analysis, and his skill in the way of counteraction. But when the idea of their existence shall have been proved in any case to be unfounded, it is generally possible to evade such obstacles by tact, or to undermine them by argument, and, most of all, to dissipate them by firmness. WILLIAM M. ORD.

IDROSIS (*ἰδρῶς*, sweat). A synonym for hyperidrosis. *See* PERSPIRATION, Disorders of.

ILIO-TYPHUS.—A synonym for typhoid fever. *See* TYPHOID FEVER.

ILEUM. Diseases of. *See* INTESTINES, Diseases of.

ILEUS (*εἰλῶς*, I twist).—A synonym for an intestinal obstruction. *See* INTESTINAL OBSTRUCTION.

ILIAC REGION.—The iliac region, or region of the iliac fossa, is limited laterally and superiorly by the crest of the ilium, anteriorly by Poupart's ligament, and internally and below by the brim of the true pelvis or inner edge of the psoas magnus muscle.

ANATOMICAL RELATIONS.—That portion of the abdominal cavity which corresponds to these boundaries, contains the following viscera on the right side:—the cæcum, the vermiform appendix, some coils of the small intestines, and the ureter; and on the left side:—the sigmoid flexure of the colon and small intestines, and the ureter.

In front of the cavity is the ilio-inguinal region, which forms its anterior parietes, and from which surface all examinations of the region are instituted. Exploration is difficult in obese persons, and to facilitate it we must relax the abdominal parietes by flexing the thigh, and by pressing the fingers immediately above the crural arch.

The *peritoneum* is but very slightly united to the subserous tissues, and is easily separated from them. It completely covers in the left iliac fossa; but on the right side, owing to the presence of the cæcum, this investment is incomplete (*see* LUMBAR REGION).

The *sub-peritoneal cellular tissue* may be regarded as being composed of two distinct layers. The first, immediately beneath the peritoneum, is a continuation of the lax cellulose-fatty envelope of the kidney and cæcum, passing with the femoral vessels into the crural canal, and with the spermatic cord into the scrotum. The deeper or sub-aponeurotic layer lies beneath the sheath of the iliacopsoas muscle, being continuous above with the sub-plural cellular tissue, and accompanying this muscle downwards as far as its insertion into the lesser trochanter.

The *arteries* of this region are the common and external iliac, and their branches.

The *nerves* of the iliac fossa are the lumbar plexus (the trunks of which lie in the iliacopsoas muscle) and its branches, and the solar, renal, hypogastric, and lumbo-aortic branches of the sympathetic.

The *fascia ilioea* is attached above to the entire inner lip of the iliac crest. Internally it is blended with the sheath of the psoas at the level of the promontory of the sacrum; and below this point it becomes fixed to the brim of the true pelvis, passing behind the vessels and giving off a thin cellular lamella in front of them.

The *sheath of the psoas muscle* is attached above to the ligamentum arcuatum inferum, it encloses the psoas anteriorly (the posterior portion of its envelope being formed by the lumbar vertebrae), it is blended externally with the sheath of the quadratus lumborum; whilst internally it is attached to the anterior common ligament. Inferiorly it is continuous with the fascia ilioea.

The *osseous layer* corresponds with the iliac bones.

PATHOLOGICAL AND CLINICAL RELATIONS.—The viscera which have been enumerated above, as being contained in the iliac region of the abdomen, present various diseased conditions, which cannot be satisfactorily diagnosed without a practical knowledge of its anatomical relations, and especially of the fasciæ, sub-aponeurotic, and aponeurotic structures of the iliac region. Thus in the right iliac region the physician meets with tumours and other diseases of the cæcum, vermiform appendix, and lower part of the ileum, including the local lesions of typhoid fever (*see* CÆCUM, Diseases of). In the left iliac region, the diseases of the sigmoid flexure possess equally important relations. The tumours, extravasations, and abscesses, which may commence in the pelvis, frequently make their way into either iliac region; and this is also the seat of morbid conditions connected with the ureter in the middle portion of its course, as well as partly of the psoas in renal calculus. In the sub-peritoneal tissue we meet with bloody or urinary infiltrations, focal abscesses, and perityphilitic or idiopathic abscesses independent of any intestinal lesion. Collections of pus beneath the fascia are generally dependent on caries of the vertebrae, and may either be confined to the iliac fossa, or lie within the sheath of the psoas muscle (psoas abscess).

Again, lumbar abscesses may point anteriorly, and be diagnosed by palpation of the abdominal walls.

This region is the seat of ligature of the common, external, or internal iliac arteries. The pulsation of the two former can generally be felt; and it must be borne in mind that the abdominal aorta pulsates in the left iliac region.

EDWARD BELLAMY.

ILLUSION.—A false or mistaken perception of one of the senses, as when a person sees or hears something, and takes it to be something else. The term has been used as synonymous with delusion and hallucination. Illusions may occur in the sane as well as the insane. See HALLUCINATION.

IMBECILITY. See DEMENTIA; and IDIOCY.

IMPETIGINODES.—Impetiginous, that is, having the character of impetigo, hence, eczema impetiginodes. See IMPETIGO.

IMPETIGO.—SYNON.: Fr. *Impétigo*; Ger. *Eiterflechte*.

DEFINITION.—A term used by Celsus and Pliny, apparently signifying *an impetu agens*, that is, breaking out with violence or impetuosity. In modern dermatology the term is restricted to an eruption of small pustular vesicles, accompanied with but little redness or inflammation, and that of a superficial character, hence, the individual pustules have been termed *pyodracæ* or 'cold pustules,' in contradistinction to the pustules of ecthyma, which are termed *phlyæcæ*, or 'hot' and inflammatory pustules.

ÆTIOLOGY.—Impetigo is an outbreak of a sensitive and weakly skin, associated with nutritive debility; and is more common in children and women than in men.

VARIETIES.—Impetigo presents itself in three forms. First, it occurs as an eruption of isolated pustules, distributed more or less generally, when it is called *Impetigo sparsa*. Secondly, it is found as a congregation of pustules forming blotches, rarely exceeding one or two inches in diameter, constituting *Impetigo conferta* and *Impetigo figurata*. And, thirdly, it is seen as a complication of eczema, representing a pyogenic tendency, as *Eczema impetiginodes*. In children it is apt to occur on the face, hands, and feet, and particularly in the region of the mouth, nose, ears, and, from its frequent spreading through a whole family or neighbourhood, has awakened a suspicion of contagion, and as such, received from the late Dr. Tilbury Fox the name of *impetigo contagiosa* (see IMPETIGO CONTAGIOSA). Dr. Fox likewise detected epiphytes in this form of eruption. Nevertheless, impetigo will best be regarded as a simple pyogenic eczema, and not ordinarily contagious.

DESCRIPTION.—Pathologically, impetigo is a vesicle containing pus or a mucopurulent fluid, rather than a true pustule, and varies in size from a mere point, not larger than a pin's head, to a hemisphere of a quarter of an inch in diameter. With the smaller dimension, it often occupies the aperture of a follicle; whilst when more extensive, it spreads over the surface occupied by several of these apertures. The colour of its contents likewise varies in dif-

ferent specimens, being sometimes brightly yellow, at other times cream-coloured, and in the 'epidemic' variety almost colourless. After a few days the secretion dries up into a crust, of yellowish or brownish colour; and the crust varies in figure and thickness according to the activity of the secreting process, or the undisturbed condition of the pustules. On the face of children it will sometimes dry up into a crust of considerable dimensions; and in this state, when it retains its yellow colour, is an example of what the ancients denominated *melitagra*. More frequently, however, the crust is discoloured and blackened by admixture with blood, and when associated with eczema, is capable of forming a mask over the whole face—*Impetigo larvæ*—or, in the case of infants at the breast, an impetiginous *crusta lactea*.

PROGNOSIS.—The prognosis of impetigo turns upon the fact that it results from nutritive debility. It is perfectly curable, is by no means grave in its nature, and disappears completely when the health and strength of the patient are restored; in ordinary cases, in two or three weeks.

TREATMENT.—If any derangement of digestion and secretion be evident in a case of impetigo, this should be regulated before topics are resorted to. The diet and regimen should be nutritive and wholesome, while the tonics most suitable to such cases are iron, quinine, arsenic, nitrohydrochloric acid, and cod-liver oil. Locally, the blotches should be kept covered with the oxide of zinc ointment, or with a lotion of lime-water and oxide of zinc. The former of these remedies preserves the softness and pliancy of the crust; whilst the latter dries them up. Both processes promote their removal; and in the selection of the remedy the best guide will be the amount of discharge, the degree of irritability of the skin, and especially the sensations of the patient.

ERASMUS WILSON.

IMPETIGO CONTAGIOSA (*impetigo*, a scabbing disease of the skin, *contagiosa*, contagious)—**DEFINITION.**—A contagious vesicopustular disease; sometimes epidemic; attacking children in the vast majority of cases; and often affecting several members of the same family.

SYMPTOMS.—This disease, which was first described by the writer, is sometimes attended at the outset with pyrexial disturbance. The eruption first makes its appearance about the face, and indeed is chiefly marked in this situation; but it may appear on the neck, head, and limbs, and more rarely on the trunk. The eruption is composed of one or more crops; and begins by the formation of vesicles, which develop into little bullæ. The contents of these become milky, and then sero-purulent; and speedily dry into light-yellow scabs which look as if snuck on, unless the spots are injured by scratching. Mothers describe these little vesicopustules in their early stage as 'little watery heads' or 'watery pocks.' The significant features of these spots are their separateness; their superficiality; their replacement by the flattened scabs; and the contagious quality of the fluid contents of the vesicopustules. Very often bullæ appear about the hands of the children affected.

Y Y

TREATMENT.—The treatment of contagious impetigo consists in applying the unguentum hydragryi ammoniaci in a diluted form to the red surfaces beneath the scabs, by which the characters of this secreting surface are altered, so that the disease is not spread by auto-inoculation. As each spot tends to run a definite and short course, the whole disease is quickly cured by the prevention of its spread in this manner. The general health may require attention. TILBURY FOX.

IMPOTENCY (*ra*, not, and *potens*, capable).
 СЛОВО: Fr. *Impuissance*; Ger. *Impotenz*.

ÆTIOLOGY AND PATHOLOGY.—Impotency implies an incapacity for sexual intercourse, and it arises from various causes. The testicles are the organs which furnish spermatozoa, the element essential to impregnation. Their functions may become suspended, or be incapable of excitement; or they may be exerted to excess, improperly excited, and so abused as to fail prematurely; or these organs may become impaired or destroyed by disease.

The impulse for commerce with the other sex exists in different degrees of force in different men. A certain degree of vigour is necessary to bear the nervous excitement attending it, hence in advanced years, and in weak and susceptible individuals, the frame is unable to sustain frequent coition with impunity. Rules have been given for regulating the sexual functions, and restricting their exercise within due bounds. They are, however, of little value, for the powers vary greatly in different persons, and also at different periods of life, and what is moderation in one man, or at one period of life, is excess in another man, or at another time of life. Whenever the sexual act is followed by a prolonged sense of debility and lassitude, an uncomfortable feeling in the loins, and disinclination for either physical or mental exertion, the limits consistent with health have been exceeded.

In adult persons of recluse and studious habits the testicles often continue dormant for years. Like the mammae in the unmarried female, though inactive, they remain sound and competent for secretion when duly excited and called upon to exercise their functions. The case is different later in life. Thus widowers, after remaining chaste for some time, on marrying have been doomed to disappointment. Inaction has hastened the natural decline. After middle age, as life advances, the testicles diminish in size, and become soft and flaccid; the secretion of semen becomes languid; and the desire and power to indulge in coition gradually subside. The period of life at which these changes become marked varies in different men, but most persons are conscious of some decline in sexual vigour after the age of forty. There are some remarkable instances on record of men who are reported to have been capable of the reproductive act in very advanced life. Cato, the censor, is said to have had a son at eighty years of age. Zadislaus, king of Poland, at the age of ninety, married his second wife, and had two sons. The writer has often detected spermatozoa in the fluid from the testicles of very old men, one a tailor aged eighty-seven. Duplay discovered them in nine octogenarians. Though the scantily secreted sperm

may retain its fecundating properties, old men may still fail in the other conditions essential to the due performance of the sexual functions.

The testicles are under the influence of the brain, which animates and controls the desire for sexual intercourse. An emotion of the mind, as sudden disgust or anger, arrests the secretion of these glands as quickly and as effectually as a strong mental impression stops the secretion of gastric juice, and takes away the appetite for food. An attack of apoplexy, or severe injury to the head, may extinguish all desire as well as capacity for coition. A gentleman, aged thirty-four, had a concussion of the brain which rendered him insensible for twelve hours. For four months afterwards he lost all sexual power, and on his recovery it remained feeble. There are several cases on record in which severe injury of the head has been followed by complete wasting of the testicles, as well as by permanent impotency. Diseases and injuries of the spinal cord, producing paraplegia, have no direct effect on the testicles, but destroy the power to copulate.

Some men are but little susceptible to the influence of the female sex, and though of vigorous mould, they have not only passed a life of absolute chastity, but have never evinced the slightest disposition for sexual enjoyment. This arises probably from some cerebral imperfection. Owing to the same cause, the testicles may remain undeveloped in adult age, attended with an absence of sexual desires. Cases of wasting of the testicles after injuries of the head, and the non-development of these organs, with absence of the venereal appetite, in certain erotics and idiots, tend to strengthen this view.

The most common cause of impotency is want of self-confidence—excessive apprehension of inability to perform well the duty of the sex, a feeling which is often greatly aggravated by the perusal of the productions of quacks and other impostors. When persons entertain these groundless fears, it may be long before success attends their efforts, every failure adding to the evil by diminishing the reliance upon their powers. In the case of persons recently married, who may be affected with this form of impotency, a tonic may be prescribed, and the patient be directed to abstain from all attempts at intercourse whilst under treatment, and we may rest satisfied that not many days will pass over before nature asserts her empire. These cases must not be lightly treated. The patient is in great distress of mind. The true cause of failure may be explained to him, and he may be confidently assured of the groundless character of his fears, and of the influence of his doubts and apprehensions in preventing him from fulfilling his desires. Encouraging assurances will do more in effecting a cure than stimulating medicines or any sort of medical treatment. A single success banishes at once all his fears, and gives security for the future.

Excessive exercise of the sexual functions is a frequent cause of impotency, and its too early indulgence often entails a loss of power in middle age. This is often the case in the despotic countries of the East. Another result of inordinate excitement of the organs is frequent involuntary discharges of the spermatic fluid. Varicocele tends gradually to impair the nutri-

tion, and diminish the secreting powers of the testicles. When limited to one side, as usual, a varicocele need not disturb the mind of the patient. Diseases which destroy the substance, or produce wasting of the testicle, necessarily prevent its secreting. The functions, however, of this gland are not very readily impaired by disease, and as long as a small part remains entire, the organ may be fitted to perform its office sufficiently for the end destined by nature. A person who has lost both testicles by operation after arriving at puberty, may experience desire, have erections, accomplish coitus, and even emit fluid for many months and even years afterwards, but he soon loses the capacity to impregnate, and all sexual power gradually subsides.

Virility is more or less affected by constitutional diseases. Few complaints have greater influence in impairing the generative functions than those of the kidney. Diuretics, as the nitrate of potash, carbonate of soda, &c., are well known to act as aphrodisiacs. In irritative dyspepsia, with deposits in the urine of earthy phosphates or oxalate of lime, there is generally some inability. Impotency in these cases is only one of the manifestations of defective assimilation and depressed vital force. The treatment of such cases by mineral acids and other remedies calculated to improve the general health is very successful in restoring sexual vigour. In diabetes and albuminuria the reproductive organs are weak and often quite inactive, but may regain tone as the kidneys are restored to a healthy state.

Impotency sometimes occurs in middle life without any obvious cause. In such persons the writer has noticed a constitutional change similar to that which occurs in eunuchs, but less marked. They have been observed to grow sleek and corpulent, to have a scanty beard, and to be indisposed to active muscular exertion. In general they evince no unhappiness at their altered condition. In atonic impotency, the external organs afford indications of the want of power. Not only are the testicles soft and flaccid, from the absence of blood in the vessels and sperm in the tubes, but the penis is small and shrivelled, and the glands relaxed. The scrotum is also loose. These parts are pale, feel cold, and their sensibility to contact is diminished.

Treatment.—Certain medicines, reputed to possess the property of stimulating and invigorating the sexual organs, have been classed as *aphrodisiacs*, and some of them are said to be used, especially in the East, by the sensualist, to excite the organs when exhausted by satiety and excess. Several act on and stimulate the urinary organs, and thereby give temporary power to the function of erection; but they produce little or no effect on the special sexual organs. They determine blood to the penis, and cause morbid erections, without any voluptuous sensations and desires. Such appears to be the character of the influence produced by cantharides, the most common of this class of medicines, and the chief ingredient of quick medicines for impotency. There are, however, certain cases in which cantharides is useful. In an atonic state of the organs, in which the erections are feeble, unstable, and insufficient to fill ten minutes of the

tincture may be given every three or four hours for a short time before the occasion arises for the exercise of the sexual functions. Dilute phosphoric acid, the phosphate of iron, the liquor strychnine, and eight of zys are remedies which may be given in impotency. The conditions to which these aphrodisiac remedies are chiefly applicable is when the intromittent organ is but feebly excited, and does not maintain the physical state necessary for penetration, during the period of congress. Such torpidity may exist in persons in whom desires are at times strongly felt, and the functions of the testicles properly performed. In these cases, also in timid persons, and in others whose organs are inexcitable from long disuse, stimulating treatment may conduce to success, and ensure confidence for the future. But these remedies exert no influence in a constitutional apathy of the sexual functions. They have rarely, also, more than a temporary effect; and in persons advanced in life, when the parts, having fulfilled their office, are experiencing their natural decline, they operate injuriously, and tend to produce congestion of the prostate and local disease. In those cases also in which the sexual organs are weakened or prematurely exhausted by excess, they are likewise hurtful, as well as fruitless. After such abuses a period of repose is required, and by the avoidance of all sources of excitement, and by diet and remedies adapted to invigorate the body, such as the preparations of steel, a gradual restoration of the procreative functions may be hoped for.

Electro-magnetism is a remedy of some efficacy in certain forms of impotency. Interrupted currents (Faradic) may be passed in two directions, from the perineum to the glans penis in cases of defective erectile power, and from the groin along the spermatic cord to the testicles, in cases where those organs are soft and flaccid, and where secretion is languid. The results are often disappointing. In cases in which the desires are strong, but the erections feeble, the sensibility of the glans penis is so lowered that the friction of coition is incapable of maintaining prolonged distension of the organ, and erection subsides shortly after penetration and before completion of the act. A few applications of the electric current, by rendering the glans penis more sensitive, may cause a more persistent distension of the organ under the natural excitement. Electro-magnetism succeeds more frequently in impotency of this character than where, in addition to defective erection, the desires are feeble, and the testicles soft and inelastic; and yet the repetition of the remedy has succeeded in some instances of this less hopeful kind in rousing a dormant power, causing secretion to be resumed and erections to return. The special treatment required in cases due to injury of the central nervous system, after recovery from head-symptoms, is the use of electro-magnetism, applied from the occiput along the spine.

T. B. OUELING.

IMPULSE (*impello*, I thrust forwards).—A sensation of a stroke communicated to the hand, for example, by the action of the heart or the pulsation of an aneurism; or by the sudden movement of a fluid when agitated in any way

(see PHYSICAL EXAMINATION). The term is also employed in connection with a mental condition in insanity. See INSANITY, Varieties of.

IMPULSIVE INSANITY. See INSANITY, Varieties of.

INCARCERATION (in, in, and career, a prison).—A condition of hernia in which it cannot be reduced, on account of obstruction at the neck of the sac or from some other cause. See HERNIA.

INCOHERENCE (in, not; con, together; and aereo, I stick).—Inconsecutive or 'wandering' thought, as expressed in speech. See CONSCIOUSNESS, Disorders of.

INCOMPETENCE (in, not, and compelo, I meet accurately).—In its general sense this term signifies inability of a part to perform its functions. It is mainly applied to imperfection in the closing apparatus of an orifice, such as the valves of the heart or the pylorus. See HEART, Valves of, Diseases of.

INCOMPRESSIBLE.—Incapable of perceptibly yielding to pressure. Usually applied to the pulse. See PULSE.

INCONTINENCE (in, not, and contineo, I hold).—In medical language incontinence signifies inability to retain the urine or feces, so that they are discharged involuntarily. See DEFECATION, Disorders of; and MICTURITION, Disorders of.

INCUBATION (incubo, I hatch).—DEFINITION.—The development of disease from infecting particles, and the time occupied in the process.

PERIOD OF INCUBATION.—The period of incubation is the interval between exposure to infection and the appearance of the resulting disease. It is divided into two stages, those of *latency*, and of *incubation*; the one has reference to supposed changes in the infecting particles, the other to noticeable changes in the health of the person infected; the first stage is of variable duration and without definite symptoms, while in the second the disease is progressing and the patient is said to be sickening for it, its duration being nearly constant for each special disease. The division is not well-marked, there are changes in the so-called latent period which do not always escape detection, while those of the invasion have often to be considered as part of the disease. Where the latent stage is much prolonged a *dormant* period is inferred, for it is possible that infection may remain in the body for a time dormant; this term is only applicable to certain conditions under which infection is transmitted, and instead of speaking of the long intervals of inactivity at which epidemics recur as periods of latency or of incubation, it is to these periods of quiescence that the term dormant should be restricted.

The results of septic infection are manifested in the body without any true incubation.

Incubation properly refers only to the latent periods of infection in the acute specific diseases, still it is usual and often convenient to reckon the period of incubation as extending to the full development of the more characteristic signs of each of these diseases.

The duration of this period differs for different

classes of infectious diseases, and in a less degree for each disease; it varies within certain limits for the same disease, but is sufficiently constant to afford some distinctive characters useful in diagnosis and a knowledge of which is essential to preventive medicine. The germs of all the incubative diseases are reproduced in the bodies of the sick; to stop infection the susceptible who have been exposed to it should not mix with others till the incubation-period has passed without signs of illness. Hence it is important to ascertain the laws regulating the incubation of each specific infection, and to define the limits of variation. The invasion-stage of all these diseases is already infectious.

1. *Varicella* and *Accusua*.—In small-pox, after infection, the eruption occurs in fourteen days, and marked illness begins two days sooner. This is so well established as to afford a guide to the source of infection, by which it may frequently be discovered. Dr. Gregory's experience only furnishes one case in which the interval was prolonged to fifteen days. As short an interval as twelve days may be met with, though rarely, in small-pox modified by vaccination or by a previous attack. Small-pox by inoculation is developed in nine days, a local vesicle appears on the fourth day, there is glandular sympathy on the sixth, and febrile disturbance on the seventh and eighth days. Exactly this course is observed in vaccinia resulting from vaccination.

2. *Varicella*.—Chicken-pox has an uncertain incubation-period, varying from ten or twelve to fifteen or even nineteen days. The eruption begins with the first symptoms of illness.

3. *Morbilli*.—Measles has twelve days of incubation, reckoning to the appearance of the rash, or eight days from infection to the sickening; the latent period may be only four or six days, that of invasion may extend to six instead of four days. The general experience of schools and hospitals gives ten days from rash to rash, which is twelve days for incubation. Measles results from inoculation in seven or eight days; the shortest instance from infection, one of fifty cases traced by the writer, was eight days, the two longest, sixteen and eighteen days, but it may possibly extend to twenty-one days.

4. *Rotheln*.—Rotheln has an incubation-period of not less than ten to fourteen days, frequently extending to seventeen or twenty-one days. Very little illness precedes the rash.

5. *Mumps*.—Mumps usually takes from fourteen to twenty-one days for incubation, the shortest period is ten days; the longest that has come under the writer's observation was twenty-two days. Symptoms referable to the invasion-stage may be noticeable for a week before the swelling of the parotids; the latent stage may continue from eight days to twenty.

6. *Pertussis*.—This generally has one week, or even two, of incubation before the first febrile and catarrhal symptoms appear; there is often a latent period of only four or five days, as some cough may precede the fever, the distinctive cough is seldom heard till after the second week, the shortest period in which it has been known to occur is eight days.

7. *Influenza*.—Influenza has a very short incubation-period, reckoned by hours.

8. *Scarlet Fever*.—Scarlet fever has a short incubation-period; from three to five or six days is the time in which the disease is usually declared; it may appear in less than two days; the longest interval is seven or eight days. There are instances where exposure to this infection has produced no effect until after some accident or surgical operation, the rash then appearing in from three to five days. Supposing infection to have been received a week previously, twelve days would not be too much to allow for such possible extension of the incubation-period. After removal from a source of scarlet fever, those who have no symptoms of the illness within one week will generally escape.

9. *Diphtheria*.—Diphtheria may be developed in three or four days; an interval of from six to eight days is not unfrequent. Sometimes two or three days' fever precedes the first local signs, or these may appear at the very commencement, and the incubation be reduced to a single day. On separating the healthy from the sick, more than a week must elapse before immunity can be predicated.

10. *Typhoid Fever*.—In enteric fever, the occurrence of the first symptoms in a large number of cases, traced by Buchanan, was eleven days after the operation of the cause, many other cases occurring two or three days later. Dr. Hunter of Lanthgow gives one case, with a single definite exposure, where the prodromata occurred in the early part of the third week with a rigor at the end of it, twenty-one days elapsing before the fever was marked; certain interruptions to the febrile process may still further prolong the interval. An incubation-period of only five days has been noted, once from contaminated milk, and once from infection; there are instances of an eight days' incubation when some of the poison has been inhaled.

11. *Typhus*.—Typhus has, in the great proportion of cases, twelve days of incubation. The late Dr. Murchison gives three cases that have exceeded this period by two or three days, and one of twenty-one days, ten of his cases fell short of it by two, six, or eight days, one of these did not exceed two days, and in two of them the latent period must have been a few hours only. The distinctive rash appears on the fourth or fifth day of illness.

12. *Relapsing Fever*.—This fever has five days of incubation, this exactly agrees with the life history of the *spiroillum* observed in the blood during the fever, the incubation-period may, however, be prolonged to seven, nine, or twelve days, or shortened to two days, many cases have succeeded almost immediately on exposure to a concentrated infection.

13. *Plague*.—Plague is communicated in from two to five days, the fever may commence on the first day, the glandular swellings on the third, or sometimes glandular tenderness begins with the fever. A period of four days suffices to set up the constitutional symptoms when the plague is conveyed by inoculation.

14. *Yellow Fever*.—Yellow fever has a short incubation of from two to six days, rarely exceeding eight days. Dr. Cargill of Jamaica gives a case fatal the day after exposure to infection.

15. *Dengue*.—Dengue is quickly developed, usually in three days. The febrile ingress is sudden, and precedes the rash only by a few hours.

16. *Cholera*.—Incubation in cholera lasts from a few hours to four days. The reports of numerous commissions give from one to five days; within five days, before the third, and not later than the fourth day. Individual cases often fall on the second or third day; the premonitory diarrhoea should be considered as part of the disease.

17. *Malaria*.—The infection of true malaria is not given off by the bodies of the sick, but limited to certain localities. This kind of miasm, to which the term infection is sometimes improperly restricted, has a marked period of incubation, which is often a lengthened one. The non-contagious malarious fevers of the West Coast of Africa often show an incubation-period of ten to twelve days. In July, 1810, our troops in Sicily fell ill with remittent fever thirteen or fourteen days after exposure to malaria. Men continued to fall ill for twelve days after their removal from the infected site. Labourers going to our son-districts for the harvest seldom had ague till the end of their month's work, and often not till two or three weeks after their return. Ague may not appear till months after residence in a marshy district.

18. *Syphilis*.—The induration of a syphilitic sore appears after ten days, six weeks later the rash or sore throat. The localised changes of the incubatory period may occupy from three days to three weeks or even longer; in the shortest instances with immediate adenopathy the eruption follows in six weeks. John Hunter gives the interval from the local to general infection as two months, this may extend to eighty days. Other constitutional symptoms occur at much longer intervals. The contagion of secondary syphilis requires five weeks or longer to become manifest.

19. *Rabies*.—Hydrophobia presents us with the longest, and also with the most variable period of incubation, this, however, has a limit of great practical value; the shortest interval known is a fortnight, so that ill effects felt in a less time than this, or following rapidly after the bite, are readily distinguished from rabies. The usual period of incubation is six weeks. Three weeks is an exceptionally short period, three months not exceptionally long. Dr. Mead gives cases occurring after eleven and fifteen months. An interval of thirteen years has recently been recorded. After the second month has elapsed the fear of any ulterior consequences becomes less and less. In the dog the usual interval is from three to six or eight weeks; it has occurred after three months, and in one instance recorded by Youatt after seven months. The shortest interval given by Regnault, from the bite to signs of rabies in the dog, is ten days; of his sixty-eight cases ten were from a fortnight to three weeks, and fifty-seven at longer intervals.

The incubation-periods of these widely-differing diseases, while retaining distinctive differences, merge into each other. The longest intervals observed for scarlet fever and diphtheria correspond with the shortest observed in measles and small-pox, while the longest in these diseases

and in mumps come near the shortest period for hydrophobia or ague. Many important diseases are separated widely and distinctly by their length of incubation, as small-pox from cholera, yellow fever and plague from typhus, and still more widely from the recurrent paludal fever.

WILLIAM SQUIRE.

INDIAN RINGWORM. See EPIPHYTIC SKIN-DISEASES.

INDICATION (*indico*, I point out).—That which suggests or clearly demonstrates the course to be pursued, and the remedies to be adopted by the practitioner, either for the prevention, or in the actual treatment of disease.

INDIGESTION.—Difficulty in digestion. See DIGESTION, Disorders of.

INDURATED CHANCER.—A synonym for hard chancre. See SYPHILIS.

INDURATION (*induro*, I harden) — A term applied to the process or condition of hardening of the tissues from any cause.

INFANTILE CONVULSIONS. — See CONVULSIONS; and INFANTS, Diseases of.

INFANTILE PARALYSIS. — SYNON.: *Fr* Paralyse essentielle de l'enfance (Lisborne); *Paralyse atrophique grasseuse de l'enfance* (Duchenne); *Ger* Kinderlahmung.

ÆTIOLOGY.—This is a disease which affects children at an age varying from a few months to a few years, and commonly during the first dentition. Antecedent events, such as falls, injuries, and dentition, have been assigned, but on no sufficient evidence, as causes of this lesion; and beyond the fact that infancy is a distinct predisposing cause, almost nothing is positively known in regard to the ætiology of this affection. Its onset is often quite sudden, in the midst of what appears to be perfect health.

ANATOMICAL CHARACTERS.—Recent microscopical investigation of the spinal cord and muscles has thrown much light on the morbid anatomy of infantile paralysis. In most cases the atrophied muscles are found to have undergone fatty degeneration, with disappearance, to a greater or less extent, of the transverse striae. Oil-globules and numerous fat-cells are also found between the fibres.

It has been shown by the investigations of Cornil, Prévost and Vulpian, Charcot and Joffroy, and the writer, that in fatal cases of infantile paralysis the spinal cord and its nerves are affected by a variety of lesions. These morbid changes consist of atrophy of the anterior cornua and their nerve-cells; of granular disintegration and atrophy of the anterior nerve-roots, and of atrophy of the anterior columns, particularly in the cervical and lumbar enlargements, where the nerves that supply the atrophied limbs are given off. Corpora amylacea have also been found both in the white and grey substances.

SYMPTOMS.—Infantile paralysis is usually preceded by pyrexia, and more or less pain in the back. The attack is generally sudden, and sometimes is accompanied by convulsions, which are at once followed by paralysis, but without loss of sensibility. The lower extremities are

generally the first invaded, and the paralysis rarely attacks the upper extremities alone. In the beginning it is more or less generalized, but after a time it becomes limited to groups of muscles, to particular muscles, or to one member. The muscles most prone to be affected are those at the anterior part of the leg—the extensors of the toes, and the flexors of the foot, the extensors and supinators of the hand; the extensors of the leg, and the muscles of the foot. In some instances the disease fixes on single muscles, particularly the extensor digitorum pedis, the tibialis anticus, the sterno-mastoid, or the deltoid. There is a loss of five or more degrees of temperature in the parts affected, and their reflex excitability, as well as their electric contractility, is more or less diminished, and sometimes completely abolished. After a period varying from one to two or more months, the paralyzed muscles begin to waste. This wasting is much more rapid than in progressive muscular atrophy, and is in proportion to the loss of electro-muscular contractility. Bones and ligaments are also often involved in the atrophy.

After a period, varying from a few days to a few weeks, those muscles of which the structure has remained unaltered may recover their voluntary contractility, and then the paralysis disappears, but this period is sometimes more protracted. In those which regain their voluntary and electric contractility, nutrition improves, and their volume increases; whereas those muscles which remain paralyzed undergo progressive atrophy, accompanied by granular or fatty degeneration. The tonic force of those muscles, therefore, which have preserved or have recovered their contractile power, not being opposed by their antagonists, which have undergone atrophy and degeneration, a variety of deformities and unnatural attitudes gradually ensue, and call for the skill of the surgeon. The most important of these club-foot deformities are *talyas equinus*, *equino-varus*, *equino-valgus*, *calcaneus* or *calcaneo-varicus*, and *varus*.

PROGNOSIS.—This will depend on the nature and extent of the morbid changes that have taken place in the nervous centres and in the muscles. The extent of these changes can be surmised by the electro-muscular test. Just in proportion as a paralyzed muscle loses its electro-muscular contractility and sensibility does it undergo atrophy, and subsequently pass rapidly into a state of granular or fatty degeneration. If, therefore, the electric contractility of the affected muscles be lost to the induced and continuous current, the prognosis will be of the gravest character.

TREATMENT.—In the treatment of this disease both general and local means must be adopted. In the acute stage, rest in the recumbent posture is of great importance. When the muscles have become affected by paralysis and atrophy, local as well as general means of treatment must be employed. Of the local means electricity is one of the most important. If the induced current should fail to produce contraction of the affected muscles, the continuous current should be employed. Shampooing, friction, and the application of hot water to the muscles are also useful. The subcutaneous injection of mi-

ante quantities of strychnia the writer has used with great advantage in several cases. At the onset of the paralysis he decidedly recommends a repetition of blisters to that portion of the spine from which the nerves supplying the affected muscles proceed.

In the later stages of the disease, when it is manifested chiefly by paralysis and atrophy of muscles, the most approved general remedies consist of strychnine, cod-liver oil, the preparations of emulsion and iron, arsenic and phosphorus, together with attention to the secretions and excretions, and to ordinary hygienic measures.

J. LOCKHART CLARKE.

INFANTILE REMITTENT FEVER.

By some authorities a disease thus named has been regarded as a special kind of fever; but the condition is probably either typhoid fever of a mild type, or febrile disturbance accompanying disorders of the alimentary canal.

INFANTS, Diseases of.—There are few disorders which can be said to be peculiar to infancy and childhood. The diseases to which children are liable are, as a rule, those which attack older persons, and present the same pathological characters. But disease as it occurs in children does yet require especial study, for the symptoms by which it is accompanied often differ widely from those with which ordinary hospital practice has rendered us familiar. Children are not merely adults in miniature. They have special peculiarities of constitution, which impress their own stamp upon all acute diseases, and often rouse up a number of accessory phenomena which overshadow the main symptoms, and obscure a case which but for them would be simple and clear.

GENERAL CHARACTERS.—The most striking peculiarity of childhood is the marked excitability of the nervous system; for the promptness and intensity with which the whole system reacts against any source of irritation is a cause of continual embarrassment to the physician. A fragment of indigestible food, for example, may produce high fever, or alarming agitation, and even throw the child into convulsions; a slight irritation of the larynx may produce severe spasm, and simulate for the time all the symptoms of true diphtheritic croup. The beginning of acute disease is almost invariably accompanied by profound general disturbance; but disturbance as profound may be excited by the simplest functional disorder, so that the severity of the symptoms is no guide at all to the severity of the lesion with which we have to deal. In all cases, therefore, it is of importance, if possible, to pick out the local symptoms—those, namely, which point to mischief of any special organ—and separate them from others which are expressive merely of the general distress. Such local symptoms are the cough, rapid breathing, and active nares which point to acute lung-disease, the squinting and immobility of pupils which are so characteristic of cerebral affections; and the peculiar jerking movement of the legs which, combined with hardness of the abdominal muscles, betrays the existence of colicky pain. Such local symptoms are not, however, always to be discovered, and even if present may not fur-

nish trustworthy indications; for so great is the sympathy in the young child of distant organs with one another—linked together as they are by the impressionable nervous system—that the organ from which the more definite symptoms appear to arise, may not be the organ which is actually the seat of disease. The two organs which are most frequently found to present these deceptive manifestations are the stomach and the brain. The sympathy of the stomach with an irritable condition of other parts of the body continues more or less through life: the vomiting of pregnancy and of disordered uterine function in the female, and of cerebral and renal diseases in both sexes, being matter of common observation. In the child, however, this sympathy is carried to its highest point. Vomiting is a common symptom at the beginning of every acute disease, and in many children any casual disturbance is apt to be attended by it. The brain, again, exhibits a close sympathy with irritation of the more important organs. In some cases of pneumonia, notably those where the inflammation is seated at the apex of the lung, headache, vertigo, delirium, and stupor may be so marked that the ordinary symptoms of the disease are completely obscured, and the case is mistaken for one of meningitis. Again, the violent nocturnal delirium so often excited by the irritation of worms in the alimentary canal, must be within the experience of all.

The nervous excitability of children, and its influence upon the system generally, is well illustrated by the high temperature noticed in many children on the first evening after admission into the wards of a hospital. The elevation varies in degree in different children, but if the patient be not a mere infant, it is usually over 100°, although the complaint be one not ordinarily attended by pyrexia.

Perhaps, however, the most familiar instance of the impressibility of the nervous system is seen in the case of convulsions. A 'fit' in the child has a very different meaning to a similar attack in the adult. In the latter it is usually evidence of a grave centric lesion, and its occurrence occasions the greatest anxiety. In the child, on the contrary, it is a common expression of the perturbation of the nervous system, set up in response to some excentric irritation, and often, as in the case of the onset of acute disease, is analogous to the rigor which ushers in an acute attack in older persons. Sometimes, it is true, convulsions are produced in the child, as in the adult, by severe cerebral disease; but in such cases the fits are frequently repeated, and are succeeded by rigidity, paralysis, and other signs of centric irritation. As a rule, single fits, or convulsions occurring without other signs of nerve-lesion in a healthy child, are purely reflex, and have no gravity whatever.

The impressibility of the nervous system is increased by causes which produce a sudden depression of strength, such as a bad attack of diarrhoea, or loss of blood, and in one chronic disease—rickets—the nervous irritability is very great. The effect of chronic wasting upon the child is, however, usually to produce an opposite result; and under the long-continued influence of enfeebling disease the excitability of the ner-

vous system becomes gradually less and less manifest, until it finally disappears almost entirely. It is of importance to the practitioner to bear this fact in mind, for in a child much reduced by chronic illness, the presence of an intercurrent acute complication—such as inflammation of the lung—may be indicated by very few symptoms, the system having become almost insensible to nervous impressions.

Another peculiarity, which strikes the attention of anyone accustomed only to disease as it occurs in the adult, is the vast preponderance in infantile disorders of mere disturbance of function, and the disastrous consequences which may ensue from such derangements. Infants rapidly part with their heat, and are easily chilled. They are therefore excessively sensitive to changes of temperature. A catarrh is a common ailment in the young child, and is attended by various dangers according to the part of the mucous tract which is affected by it. Gastric catarrh with violent and repeated vomiting, and intestinal catarrh with uncontrollable diarrhoea, are answerable for a large proportion of the deaths amongst young children during the warmer months. Even in cases where the catarrh affecting the digestive organs is of a less acute and violent character, the issue is often very serious. The gradual failure in nutrition, which is the result of such an impediment to the digestion of food, is a common cause of wasting in young children; and unless measures be taken early to restore the proper working of the alimentary functions, the cure may end fatally. In the autumn and winter the bronchial mucous membrane is more frequently attacked. In such cases, however apparently slight may be the catarrh, a weakly infant is always exposed to the danger of pulmonary collapse, and a rapid interference with the respiratory function, such as takes place when collapse of some extent of lung is quickly brought about, is often a cause of sudden death.

It is in consequence of this frequency of functional derangements, and their dangerous character, that *post-mortem* examinations in infants are so often unsatisfactory in finding any appearances explanatory of the cause of death.

CLINICAL EXAMINATION.—The clinical examination of young children requires tact and patience, but unless the child be very unruly it is not difficult. The patient cannot himself describe his symptoms, but all necessary information can be gained from the parents. Mothers are, as a rule, good observers, and allowing for their natural anxiety and a slight tendency to exaggeration, their statements can usually be relied upon. We can thus learn the previous state of the child, the exact date at which his symptoms began, and the order in which they appeared. Infants should be always stripped for examination, so that the whole body may be exposed to view. Before, however, ordering the removal of the clothes, we should be careful to satisfy ourselves upon certain points which can only be properly observed while the child is in repose. Thus, in order to count the pulse and respiration, perfect quiet is indispensable, for the least movement quickens the heart's action, and alters the rapidity of the breathing. At the same time the temperature can be taken by the

thermometer in the rectum. The whole body should then be examined for spots or swellings; the condition of the skin can be noted—whether dry or moist; and we can ascertain the state of the belly, with regard to hardness or softness of the abdominal walls, and the size of the liver and spleen. If the child cry at the time, we mark the character of the voice, for hoarseness is an early sign of congenital syphilis.

In the physical examination of the chest in a child, it is important to attend to the following points:—To employ percussion of the two sides at the same period of the respiratory movement, that is, during expiration or during inspiration; to strike gently with *æco* fingers, for by this means a larger volume of sound is brought out, and slight dullness is more easily detected; always to use a stethoscope instead of the unassisted ear, in order to limit the area listened to; and to manage so that the child's mouth be open during auscultation, so as to hinder the transmission of sounds from the throat. In an infant the back is best examined by placing the child on the nurse's left shoulder, with his left arm round her neck. If the chin be now depressed by the nurse's hand on the child's head, the muscles of both shoulders are relaxed. The front and sides of the chest can be examined as the infant lies on his back. We must remember that the breath-sounds, especially that of inspiration, are of a more blowing quality in the child than they are in the adult; and that there is naturally less resonance at the right base, on account of the proportionately greater size of the liver.

At the end of the examination the mouth should be looked at for signs of aphthæ or thrush; and the condition of the gums, as to heat and swelling, should be ascertained. Lastly, the throat is to be inspected—depressing the tongue with the handle of a spoon. If there be disorder of the digestive apparatus, such as sickness, constipation, or diarrhoea, it must not be forgotten to examine always and carefully the discharges. The urine should not be overlooked.

DIAGNOSIS.—Diagnosis in the young child is sometimes very difficult, but it is often easy enough. Being aware of the nervous excitability in young subjects, we are prepared for evidences of general disturbance, and look for more special symptoms—such as will indicate local distress, and direct our attention to a particular organ. We are also guided by a history of the attack, as gathered from the mother, and can put our suspicions to the test by a careful exploration of the whole body. In the investigation our general knowledge of the course of disease will be of service. Thus, many disorders have known pathological consequences, and are apt to be followed by special sequelæ. Measles and hooping-cough leave behind them a tendency to catarrhal pneumonia, and a liability to tuberculous. Scarlatina often leads to acute desquamative nephritis and dropsy. Other diseases again encourage particular susceptibilities—as rickets, which renders the body exceptionally sensitive to changes of temperature, and provokes catarrhal derangements. In doubtful cases we must not forget to take prevailing epidemics into account, as the beginning of zymotic diseases is often excessively puzzling. In all cases, especially

If the patient be an infant, it is important to inquire into the hygienic and dietetic arrangements to which the child is subjected. When we are still undecided, after having exhausted all means of investigation, we must be contented to wait for further indications, and no positive opinion should be hazarded while any doubt remains.

TREATMENT.—Children, as a rule, respond well to treatment. This may be explained partly by the large proportion of mere functional derangements in the illnesses to which they are subject, and partly by the state of constant change through which the body is passing, growth and development are active in organs, and the tendency is to repair. The term treatment, however, includes far more than the mere giving of physic. A complete change in all the influences acting upon the patient—a reconstruction of the dietary, and a reformation in the hygienic arrangements, especially with regard to air, light, and clothing—will often prove of immense service, and be of far more value than actual drug-giving in furthering the recovery of the child.

In the treatment of acute illness we must remember that young children cannot bear lowering measures, but we must not therefore rush to the opposite extreme, for unless suffering from temporary exhaustion, they are far from being benefited by profuse stimulation. In the beginning of acute inflammatory diseases stimulants are injurious. Even in chronic ailments, such as rickets, where a certain amount of alcohol is often of service, wine should be given with caution, and its effects upon the digestion carefully watched; it can only be given with advantage so long as it improves the appetite, and increases the digestive power.

With regard to medicines little need be said in this place. It may be remarked that, on account of the tendency to acid dyspepsia in all children, alkalies are of especial service; and that they should be always combined with an aromatic, on account of the value of the latter in stimulating the alimentary mucous membrane, and relieving the flatulence and other painful consequences of indigestion. It is important also to remember that children are wonderfully tolerant of certain drugs, while they bear others very badly. Belladonna may be given to infants and children in very large doses. They are also more tolerant of arsenic than their elders. To the action of opium, however, they are excessively susceptible, and the drug should be given—to infants especially—with extreme caution.

EUSTACE SMITH.

INFARCT (*infarctus*, I cram in).—This term was formerly applied to any kind of infiltration of an organ, but its use is now almost confined to the expression *hemorrhagic infarct*. A hemorrhagic infarct is a firm, red, usually wedge-shaped patch, which is found in certain organs as the effect of arterial embolism, or, more immediately, of the congestion and extravasation of blood to which the embolism gives rise. *See* EMBOLISM.

INFECTION
INFECTIOUS } (*infectio*, I stain).—There
INFECTIVE }

is much ambiguity and want of precision in the application of these terms, and it is only intended here to attempt to define them according to their several uses, the reader being referred for fuller illustration to the appropriate articles. Usually, they are coupled with diseases which are known to be capable of transmission from one animal to another of a different class, or from one individual to another of the same species. In general language such diseases are said to be *infectious*, and to be conveyed by *infection*. These words are, however, often employed in a more definite and limited sense, as signifying the transmission of affections of this kind without the necessity of any direct contact between the individuals, or of any obvious application of the morbid agent to the body, or its immediate introduction into the system, this agent being conveyed through the atmosphere, and taken in mainly by respiration. This limited meaning is employed in contradistinction to *contagion* and *contagious*, which then imply direct contact, and to *inoculation*; in this sense some affections being regarded as infectious but not contagious, and *vice versa*. The word *infection* is sometimes used as synonymous with the *contagium* or agent by which a communicable disease is conveyed. An important application of the term *infectio* is that in relation to the effects resulting from certain morbid products, which have been made evident during recent years, mainly by the investigations carried on in experimental pathology. Thus it has been found that the introduction of tubercle subcutaneously will lead to the formation of a similar product in different organs of the body; and the same result may follow mere suppuration under certain conditions, as well as the accumulation in the body of caseous material. The morbid products are absorbed, and originate tuberculosis by an infective process. It is even maintained that tuberculosis may be produced in this way by merely introducing tuberculous material into the stomach, as in the form of diseased meat. Again, the inoculation of septic matter has been proved to cause septicæmia and pyæmia by a similar process. When certain morbid conditions have been established within the system, other parts, more or less distant from the primary seat of mischief, often become involved by infection within the body itself, in consequence of the products being conveyed by the blood vessels or lymphatics to these remote parts, and there undergoing further multiplication and growth. Indeed the whole system may thus become tainted, including the blood and other fluids. Illustrations of this signification of infection are afforded by cancer, syphilis, tuberculous, and suppuration, the last-mentioned not only being liable to originate secondary collections of pus, but also being the usual cause of pyæmia. *See* CONTAGION.

FREDERICK T. ROBERTS.

INFILTRATION (*in*, intr, and *filtrare*, I filter).—This term was formerly applied to the effusion of a fluid into the interstices of a tissue, especially connective tissue. Now, however, its

meaning has been extended to imply the diffusion of any solid or fluid morbid product in the midst of tissue-elements, such as is seen in calcareous, albuminoid, fatty, and tubercular infiltration. See DEGENERATION.

INFLAMMATION (*inflammo*, I set on fire).

SYNON.: Fr. *Inflammation*; Ger. *Entzündung*.

DEFINITION.—Very numerous definitions have been given of inflammation. The most generally received has been that attributed to Celsus, which gives the four marks of inflammation as *rubor, tumor, calor, dolor*; but this appears to have been really due to Erasistratus, who, according to Galen, first gave precision to the conception of simple burning, as understood by the older Greek physicians, and applied the name *φλεγμονή* (previously synonymous with *φλόγιστος*) to a swelling, which had also the characters of heat, pain, throbbing, and resistance. The definition was thus based upon the notion of *swelling*, and would hardly have taken this particular form had it been derived from superficial inflammations. Although the four 'cardinal' signs may still be recognised in what we call inflammation, the definition is best derived from a cause known to be capable of producing it, and we say that *inflammation is a series of changes in a part identical with those which are produced in the same part by injury*, and, for the sake of precision, *injury by a chemical or physical irritant*. The most evident result of a slight and temporary irritation is, in vascular parts, hyperæmia, and inflammation may be regarded as produced by a more intense action of the same cause as produces simple hyperæmia, but it is not as formerly said, a kind of, or a further degree of, hyperæmia. The minute study of inflammation is best conducted by continuous observation on transparent parts of animals seen under the microscope, especially the mesentery and tongue of the frog. No non-vascular part is equally available for continuous observation in a living state, but by special methods the process may be followed in the frog's cornea.

DESCRIPTION OF THE PROCESS IN VASCULAR PARTS.—When the mesentery or tongue of a frog is drawn out and placed under the microscope, the contact of the air soon determines inflammation; and by means which need not here be described, both the vessels and the tissue-elements may be observed for hours together. The earliest change seen in the vessels of a part thus exposed is dilatation, first of the arteries, then of the veins, the capillaries being little affected. The dilatation of the vessels is accompanied at first by acceleration of the blood-stream, most noticeable in the arteries; but the acceleration does not last more than half an hour or an hour, and it then gives place to retardation, which continues as long as the inflammation lasts. The 'primary acceleration' is, however, sometimes absent or too short in its duration to be noticeable. So far, the process is doubtless the same as in active hyperæmia produced by local irritation. Whether the first dilatation is due to direct paralysis of the muscular walls of the arteries, or to a reflex action passing through the spinal cord, or to an inhibitory action passing through nerve-ganglia in the arterial walls, is uncertain. There

need not, however, be any reflex action through the spinal cord, as dilatation may take place when the part is disconnected from the great nerve-centres.

From this point begin the phenomena peculiar to inflammation. The dilatation of arteries may go on increasing for ten or twelve hours, till these have double their original diameter and pulsation becomes very prominent in them. The capillaries look as if gorged with corpuscles, forming a quasi-solid mass. The blood-current in all the vessels becomes slower and slower, till it is almost stagnant. This condition is known as *stasis*. At the same time certain peculiarities are observed in the behaviour of the red corpuscles and leucocytes in the veins. In ordinary conditions of the circulation, the central part only of the vein (as of the artery) is occupied by the corpuscles, which move on mingled together. But during *stasis* the corpuscles, especially the leucocytes, spread over the marginal portion of the vein usually free from them, and the leucocytes begin to drag along the walls of the vein, as if adherent, till at length they form a layer lining the wall of the vessel, while the red corpuscles are carried on by the current. In the capillaries, this marginal layer is never perfectly established, though leucocytes may be seen momentarily adhering to, or moving slowly along the walls. In the arteries, no such process is observed, except (according to Cohnheim) it may be for a moment during the diastole of the pulse. When this *marginal position* of leucocytes is established, and the *stasis* is at its height, begins the process which, observed long ago by Waller, and less clearly though earlier by William Addison, was re-observed and brought into notice by Cohnheim. In the words of the last-named observer: 'On the outer contour of the wall of a vessel, usually a vein, in which the marginal layer of leucocytes is well developed, sometimes first in a capillary, is seen a small projection which enlarges in length and breadth, and becomes a roundish colourless lump. This again enlarges, puts out new pointed projections, and gradually withdraws itself from the wall of the vessel, till it is attached to it only by a long narrow stem. Finally this attachment also is broken, and we see a colourless contractile body with one long process and several shorter, with one or several nuclei, in fact, a *leucocyte*.' The same process is going on meanwhile at other points of the veins and capillaries, till at length, either quickly or slowly, the outer surface of all the visible veins becomes covered with several rows of leucocytes, while their interior shows the same appearance as before. That the leucocytes seen outside were formerly inside the veins, having simply passed through the walls, admits of no reasonable doubt, though it is often difficult for the eye to seize the precise moment of passage. In the arteries nothing of the kind is seen. In the capillaries the emigration of leucocytes is very evident, and accompanied by the passage of red corpuscles also through the walls, which does not take place in the veins proper. The latter process was observed by Stricker before the revival of the observation of emigration of leucocytes.

Accompanying the extravasation of the blood-corpuscles, there is always a copious exudation

of serum, which goes far beyond physiological limits. Affected by this and by their own spontaneous movements, the leucocytes are carried far and wide into the tissue, till the whole field, that is, the whole mesentery, is so crowded with them, that nothing else can be seen. The red corpuscles, on the other hand, remain more closely in the neighbourhood of the vessels. When the exudation, carrying with it the corpuscles, and containing, as it does, coagulable material, reaches the surface, it forms the layer or false membrane of inflammatory lymph, seen in inflammation of serous surfaces.

Cause of stasis and cell-emigration.—The processes just described mark inflammation off sharply from simple hyperæmia. The production of stasis was at one time ascribed to thickening of the blood from transudation of serum; also to coagulation in the vessels, to the adhesiveness of leucocytes; and to a change in the tissues external to the vessels. But there is little doubt that the essential factor is a change in the constitution of the vascular wall, though it is still possible that this may be connected with a change in the tissues outside. The same change, while it retards the passage of blood, makes the vascular wall permeable to the corpuscles, and favours exudation. What the change is we cannot say, but it seems probable that it is the same as the walls of vessels undergo when inadequately nourished. Two classes of experiments throw light on this point.

It has been found by Ryneck that other fluids than blood, such as milk, pass with greater difficulty than usual through the vessels of an irritated part, and that stasis can be produced in the vessels of a frog, which is kept alive by the circulation of salt-solution instead of blood in its vessels. Cohnheim has also shown that a state of the vascular walls similar to that which may be presumed to exist in inflammation, may be produced by shutting off the blood from the vessels for a certain time. He put a ligature round the tongue of a frog, and observed the vessels after the ligature was cut. If the blood had been excluded for twelve to twenty-four hours only, the vessels on the return of the blood passed into a condition of simple hyperæmia; but if longer, stagnation, marginal position of leucocytes, and extravasation of corpuscles were observed, and these phenomena were more marked the longer the ligature had remained, provided it was not long enough entirely to destroy the vitality of the part. From these experiments we must conclude that the cause of stasis and its attendant phenomena is not in the blood or the cells, but in the walls of the vessels, and that the change in these is of the nature of degeneration.

Changes of the tissue-elements.—These changes are most simply seen in non-vascular parts, which will be first considered. Alterations in cartilage-cells during ulceration were observed long ago by Goodsir and Redfern, but were not then thought to belong to inflammation, non-vascular parts being not thought liable to this process. Lately the cornea has been taken as the type of non-vascular tissues. If the cornea of a frog be irritated by touching a small spot with nitrate of silver, and cut out within from twelve

to twenty-four hours afterwards, many of the fixed corpuscles are found to be already altered. Their processes are become shorter and thicker; their bodies of irregular shape; and they often show amoeboid movements, and become converted into many-nucleated protoplasmic masses, resembling what are in some other parts called giant-cells. Finally, in their places may be seen groups of new cells, or pus-corpuscles. But there are always some cornal corpuscles which remain quite unchanged. These changes cannot be traced farther, as the cornea soon becomes turbid, and the whole field of observation crowded with leucocytes.

It is still a matter of dispute whether these changes are truly reproductive or only degenerative, and whether any new cells are really formed from the fixed pus-corpuscles of the cornea, or whether the origin of these leucocytes is the same as of those which are seen surrounding the veins and capillaries of the inflamed frog's mesentery. On the one hand, it is said that the cornea can be excised so early as to preclude the possibility of migratory corpuscles finding their way from the vessels surrounding the cornea, and that even then groups of leucocytes are found in the places of cornal corpuscles, which must have been produced by germination from them. On the other hand it is urged that, even supposing it impossible that these cells could come from the surrounding blood-vessels, the conjunctival lymph-sac contains lymph-corpuscles which might travel into the cornea. Further, the leucocytes of the blood have been coloured by injecting colouring matter into the veins, which the leucocytes take up, and cells thus marked are found among those supposed to be derived from the cornal corpuscles. Without discussing these conflicting arguments, we may say that we believe the truth to be this: that young cells, indistinguishable from leucocytes or pus-corpuscles, are formed by a process of growth, cell-division, and germination, affecting the fixed cornal corpuscles, but that the number of these is inconsiderable compared with those which, even in a non-vascular tissue like the cornea, are derived from the vessels.

The process of inflammation in other non-vascular parts, such as cartilage, has been studied in the same way as in the cornea, in all cases with the disadvantage that continuous observation is impossible. The general result is the same, namely, that changes are seen, apparently without any participation of the vessels, which are regarded by some as showing degeneration and breaking up of the fixed tissue-elements; by others as showing germination and formation of new cells, but which in any case do not play an important part in the whole inflammatory process.

Tissue-changes in vascular parts.—These, though apparently more ambiguous than in non-vascular parts, are yet sometimes susceptible of more minute study. In the omentum of mammals, changes occur during inflammation in which unbiassed observation can hardly see anything else than cell-division, growth, and germination. There is indeed reason to believe that such appearances are found normally, as evidence merely of growth, but the inflammatory changes

are distinguished from the normal by their greater frequency and luxuriance. In fibrous connective-tissue similar processes have long been observed, and since attention was drawn to them by Virchow, have been regarded till lately as showing, in the clearest manner, that the fixed cells of the tissue germinate and produce new elements. This 'proliferation of connective tissue' was regarded, especially by German pathologists, as an obvious fact, and as the explanation of many morbid processes. But it is now known that what were regarded as connective-tissue corpuscles are really spaces, which may become filled with leucocytes migrated from neighbouring blood-vessels, and when the cells proper can be seen, the latter are often unaltered. Around inflamed parts the connective-tissue is often found infiltrated with young cells, the origin of which was formerly set down to proliferation. But it seems more simple to regard this 'small-celled infiltration,' which is a very frequent accompaniment of inflammation, as resulting from migration of leucocytes from the veins and capillaries of the inflamed part. The possibility, however, of connective-tissue proliferation 'cannot be doubted; and, if it occurs, the number of elements thus produced will not, as in the case of non-vascular parts, be necessarily limited. With respect to other tissues, such as muscle, nerve, &c., very conflicting statements have been published. Some years ago numerous observations were made, supposed to show the formation of new cells from the connective-tissue stroma of inflamed parts; it was then supposed that more specialised elements, such as muscle-fibre, epithelium, &c., could not produce the same; afterwards the same appearances were seen in these tissues, and interpreted in the sense which has been explained above. The recent observations of Stricker and his pupils tend to show that the tissues take part in the formation of pus-corpuscles, in true suppuration if not in lower degrees of inflammation, but do not, we think, materially alter the views to be derived from a direct study of the inflammatory process.

Besides the twofold origin of new cells above indicated, there is reason to believe that the leucocytes emigrated from the vessels, and perhaps those produced from the tissues, further divide and 'proliferate.' Stricker and Klein have both observed actual cell-division take place under the microscope; so that some of the new cells are regarded as the descendants of emigrated corpuscles. We may compare the new cells of inflamed parts to the population of a colony, where most are emigrants, or the descendants of emigrants, but some few trace their descent from the aboriginal inhabitants.

Beyond the production of new cells, the tissues outside the vessels cannot be said to play an active part in inflammation. Their passive changes are, however, important. These are chiefly degenerative, that is, necrosis of the elements takes place, preceded by various kinds of degeneration. Connective-tissue fibres soften; muscular fibres undergo fatty degeneration; and epithelium also wastes by means of fatty degeneration, and on surfaces is shed off. Nerve-tissue and all special tissues soften, liquefy, and disappear. In places where there is a large collection of pus-

corpuscles, all tissue-elements become absorbed, and the *débris* is either carried away by the lymphatics and veins, or becomes mingled with pus. In fact, along with nutritive and germinal processes, there are destructive and atrophic processes equally active.

We must now consider the products and results of inflammation, without further distinguishing between the share of the vessels and of the tissues.

PRODUCTS AND RESULTS.—All inflammatory products result either from exudation (with or without participation of the tissues), or from new growth. The exudative products are serum, mucus, and fibrin, which by combination with leucocytes, form inflammatory lymph and pus. New growth takes place from the vessels in the form of vascular connective tissue, of which a special form are granulations. With regard to exudations, no clear line can be drawn, at any stage of the process, between serous and fibrinous exudations, inflammatory lymph, and pus; the differences being only of degree.

Exudations.—Serous and mucous exudations can only when excessive be regarded as products of inflammation. The fluids formed in inflammations of serous cavities differ from those produced in passive exudations (or dropsies), in containing more fibrin and more albumen. But inflammatory exudations vary in this respect, and are sometimes scarcely to be distinguished from simple serous effusions. The fluids poured out on serous surfaces in acute inflammation always coagulate, and even in chronic cases can often be shown to be capable of coagulation. On mucous surfaces, on the contrary, the exudation does not as a rule coagulate. That this is owing in some way to the action of the epithelium seems most probable, whether it is that filtration through epithelium alters the composition of the fluid, or whether the living epithelium prevents coagulation in the same way as the endothelium of the vessels prevents coagulation of the circulating blood. When, however, the epithelium is removed, a fibrinous layer may be produced on the mucous surface, and the same result seems to follow the application of very powerful irritants, as in croupous inflammations. Mucous exudations contain mucin, as well as serum-albumen, in variable proportions.

Fibrinous exudations, in coagulating, entangle whatever leucocytes may be either extruded with the exudation, or present in the tissues. The properties of the coagulated mass differ according to the proportion of corpuscles. Hence it was at one time usual to distinguish *fibrinous* from *corpuscular* lymph, or even to regard fibrin as a mixed substance, partly made up of corpuscles. It is now known that these differences do not show any corresponding differences in the composition of the blood, but depend upon the facility with which the corpuscles leave the vessels. The product called *inflammatory lymph* consists of coagulated fibrin entangling leucocytes, the two constituents being in varying proportions. The fibrin does not differ from that of blood-clot; and may therefore be formed in the same way by a reaction between the exuded constituents of blood. But it is not a constant product of inflammation, and hence has been thought

to owe its production to local causes—that is, to reaction between the tissues and the exudation. Thus fibrin is formed on serous surfaces where normally one of the fibrin constituents is found, and for the same reason, in connective tissue, but, as stated above, not generally, on inflamed mucous surfaces, or in epithelial structures. But since it is possible that in these cases the exudation becomes altered by filtration through the tissues, there is no reason to doubt that fibrin, or both its chemical constituents, may be exuded from the vessels. Formerly great importance was attached to this product of inflammation. It was regarded as capable of forming, by organisation, new tissues, and by degeneration, pus and other things. But it is quite uncertain whether lymph is ever, strictly speaking, organised into tissue, and the formation of pus must be considered as differing from that of ordinary lymph only in degree.

Pus.—Pus is inflammatory exudation in which the corpuscles greatly predominate, and the intermediate substance is liquid. It is thus difficult to draw a line between pus and softer forms of inflammatory lymph, but the former does not contain fibrin, nor does it coagulate spontaneously. The following analysis of pus may be taken as representing an average specimen:—

Water	887.6
Pus-cells and mucus	46.6
Albumen	43.8
Fat and cholesterol	10.9
Sodium-chloride	5.9
Other alkaline salts	3.2
Earthy phosphates and iron	2.1

1000.0

It is noticeable that pus contains a much larger proportion of fat than any other inflammatory products, or than blood. Its specific gravity is 1.030 or 1.032. The appearance of pus is well known; it is a creamy fluid, which, when normal or 'laudable' and fresh, has a very faint, not offensive odour, and no sign of putrefaction. Under certain circumstances, it has a strong ammoniacal or putrefactive odour, and is described as 'unhealthy,' or 'sanious.' When allowed to stand, all pus separates into a liquid portion or 'serum,' and a sediment consisting chiefly of the corpuscles. The serum resembles blood-serum, containing paraglobulin or fibrino-plastic substance, potash-albuminate (or casein), ordinary serum-albumen, and myosin. Other constituents of pus are protagon, chondrin, gelatin, leucin, tyrosin, and xanthin.

Pus-corpuscles.—The corpuscles of fresh newly-formed pus, as seen, for instance, on an inflamed mucous surface, are not distinguishable from leucocytes of the blood, showing active ameboid movements, and continual change of form. Most corpuscles from large collections of pus, such as abscesses, are already dead, being nearly spherical in form, with the appearance of a cell-wall, and showing when acted upon by acetic acid three or more small nuclei.

Suppuration.—While the production of individual pus-corpuscles is to be explained in the same way as that of inflammatory cells in general, there are some reasons for thinking that the formation of pus requires, in addition, more special

causes. Where a collection of pus, or an abscess, is formed, it is probable that the tissue-cells take an especially active part in the formation of new elements. Suppuration is preceded by hardening and swelling of the connective tissue, a change which Stricker refers entirely to enlargement of the connective-tissue bundles. He asserts that even in the cornea this hardening is seen in those parts where pus is afterwards formed. While, therefore, we cannot say that pus is formed solely from connective tissue, we admit that the proliferation of the tissues has a more important share in suppuration than in other forms of inflammation.

Another most important view as to the cause of suppuration is suggested, though not proved, by modern processes in surgery, which show that the entire exclusion of air containing solid particles, and any air but that which has been subjected to the action of antiseptics, prevents the occurrence of suppuration, even after severe injuries or operations. It is probable, therefore, that these septic particles or bacteria are largely concerned in the production or keeping up of the suppuration, as distinguished from milder forms of inflammation.

Vascular connective tissue.—When a part has been destroyed by inflammation, the lost tissue is replaced by the preliminary formation of a peculiar structure, consisting of a highly vascular connective-tissue framework, containing an excessive number of leucocytes. The vessels are of delicate structure, and easily lacerated. This tissue also contains nerves. It has been compared to the cellular structure which composes the embryo, or to *embryonic* tissue, but the great predominance of vessels constitutes an important difference. Such tissue always originates as an outgrowth of the vessels of the inflamed part; it grows into regular connective tissue, and is thus the most important means of replacing the tissue destroyed. When produced on a surface, and growing out in the form of tufts, it receives the name of *granulations*; and, as is well known, ulcers and cavities become filled up by it. There is no doubt that granulation-tissue may form fibrous tissue, and probably other forms of connective tissue; but it is still uncertain whether epithelial structures ever pass through this stage, and whether nervous or muscular tissue is ever thus regenerated.

VARIETIES.—The most striking differences between different kinds of inflammation are those depending upon the differences of tissues, and of the situations in which it occurs.

1. **Catarrhal.**—On mucous membranes, the exudation is mucous, does not coagulate, and contains only detached epithelial cells, with scattered leucocytes; the process readily becomes chronic; but the effect on the body as a whole is less marked than in other forms. This is *catarrhal* inflammation, a term which is with less propriety transferred to inflammations of the skin, the lung, and some glandular organs.

If catarrhal inflammation is very severe it becomes purulent, and the exudation consists chiefly of pus, little or no mucus being produced. This purulent catarrh is especially characteristic of specific inflammations of the mucous surfaces, such as virulent conjunctivitis or gonorrhoea.

2. *Croupous or fibrinous.*—Croupous inflammation is that form in which a coagulable exudation is formed upon a mucous surface. In diphtheritic inflammation there is, besides a membranous exudation, some necrosis of the mucous membrane. In these forms the tendency is to acute, not chronic, disease; and the general symptoms are strongly marked. The name croup has also been transferred to certain inflammations of the lung ('croupous pneumonia') and of the kidney, but, in the latter case especially, with doubtful propriety.

The *fibrinous* form may be regarded as the normal or usual form of inflammation of serous membranes and connective tissue.

On *serous surfaces* the lowest degree of inflammation is seen in a serous exudation, containing little or no plasma, hardly to be distinguished from simple dropsy; but there is no clear line between this and a coagulable exudation, or fibrinous inflammation. This too, if still more severe, may become purulent; and, as we see in the pericardium or pleura, a purulent may succeed to a fibrinous inflammation. Finally, vascular connective tissue, forming adhesions, is generally produced. In areolar connective tissue, and in the interstitial tissue of various organs, the same stages may be distinguished, known as *inflammatory edema*, which occurs near a focus of acute inflammation; *inflammatory hardening*, such as precedes the formation of an abscess, and, finally, either abscess itself or purulent infiltration—the two forms of suppuration in connective tissue.

3. *Parenchymatous.*—It is not so easy to define the kinds of inflammation as affecting the special elements or parenchyma of organs. The lung appears to be an exception to the general rule that epithelial surfaces show the catarrhal form of inflammation, since lobar pneumonia is a type of the fibrinous form; but it should be remembered that the anatomical structure of the air-vesicles more resembles a serous than a mucous surface, having only a single layer of epithelium; and that a catarrhal form of inflammation is always the result of mechanical injury to the lung.

The name *parenchymatous inflammation* has been given to those changes occurring in the special tissues of organs, independent of their connective-tissue framework. The only factor common to all such appears to be a granular degeneration of the protoplasm of their cells, identical with what is elsewhere called albuminous degeneration, though it may end in fatty or other degeneration. In contradistinction to this, inflammation of the connective-tissue framework is termed *interstitial inflammation*.

4. *Phlegmonous.*—Phlegmonous inflammation is the same as *acute interstitial inflammation*, that is, the formation of abscess.

5. *Indurative.*—Indurative inflammation is that in which new connective-tissue is produced in the interior of organs. This is *chronic interstitial inflammation*.

6. *Degenerative.*—This variety of inflammation hardly needs explanation.

7. *Scrofulous.*—Scrofulous inflammation is that type which occurs in cachectic persons, whose tissues are easily injured and heal slowly.

Such persons are subject to chronic inflammations, which, further, involve destruction of tissue, and in which the inflammatory products readily undergo degeneration, unless these characters of destruction and degeneration are present, the name scrofulous has no precise meaning. *Strumous* is a word better forgotten, being synonymous with scrofulous, and liable to be misunderstood.

8. *Infective.*—Infective inflammations are those produced by the passage into the blood of infective matter derived from some previously existing inflammation. Pyæmia is a type, perhaps also tuberculous.

9. *Chronic.*—Most inflammations have at first a typical course, reaching their acme and then declining. If the decline is not followed by resolution they become chronic. Others, again, show from the first the character they all along maintain. Chronic inflammations are usually distinguished by the persistence of that condition of the vessels which permits exudation and cell-emigration, with less hyperæmia and general fever than in the acute form. On mucous surfaces the chronic form differs little from the acute, except in those two respects. In serous membranes chronic inflammation produces fibrous adhesions, with little or no liquid exudation. In the interstitial tissue of solid organs a large amount of new connective-tissue is produced by chronic inflammation, which first compresses the special elements, causing them to waste, and then contracts in bulk, so that the organ becomes atrophied, and usually harder and more fibrous. This is the process called 'fibroid degeneration,' as in cirrhosis of the liver. 'Chronic parenchymatous inflammations' are simple degenerations, as seen in the kidney.

Terminations.—The most favourable termination of inflammation is what is called *resolution*, in which the vascular phenomena and tissue-changes decline together, and pass away without leaving any tangible material result. Even in the apparently most perfect cases of resolution, there is little doubt that products of exudation remain when the vascular changes have subsided, and are slowly removed by the lymphatics. Other so-called terminations are *necrosis*, or total death of the part; and partial destruction by suppuration or *ulceration*. But if any loss of substance occurs, the inflammatory process cannot be regarded as at an end till the loss is wholly or partially restored by newly-formed connective-tissues. Where there is no destruction of tissue, but only masses of liquid or solid exudation, the inflammation is not, strictly speaking, resolved till these are removed. Very frequently an acute passes into a chronic inflammation.

СОНЕЖЕНІЯ.—(1) *Local consequences.*—If an inflamed part does not simply return to its original state, *atrophy* is the most common consequence. *Hypertrophy* can hardly be said to occur in the part actually inflamed, though it may in adjoining parts, as we see in enlargement of bone from periostitis. False hypertrophy, from new formation of connective-tissue, is common, but as such tissue contracts, the final result is atrophy. The hardness of this tissue causes *induration* to be put down among the consequences of inflammation.

(3) *General consequences.*—The effect of inflammation on the whole body is to produce the condition of *fever*, which is discussed in another part of this work. It will suffice here to say that fever involves raising of the body-temperature, weakening and acceleration of the heart, and disturbance of the nervous system, as well as of all the nutritive processes. It was formerly supposed that local inflammation produced fever simply through the increased production of heat by more rapid tissue-change in the inflamed part; this process raising the temperature of the blood passing through the part, and thus of the whole body by means of the blood. But this simple explanation is not adequate. It has even been much disputed whether the heat of inflamed parts ever surpasses that of the blood. The temperature of inflamed external parts is higher than the normal in that situation, or than that of a corresponding part, not inflamed, on the other side of the body. But this is also the case in hyperæmia, in which condition the external temperature never surpasses that of internal organs. Experiments on inflammation have led to very conflicting results: those of Simon and Weber being directly opposite to those of Jacobson and others. But even if we assume an actual production of heat in inflamed parts, this will not be enough, as is shown by calculation, to account for the rise of temperature in the whole body. It has also been supposed that some fever-producing or *pyrogenic* substance passes into the blood from every inflamed part, and causes increased tissue-change, with consequent increased production of heat through the whole body. But till the pyrogenic substance is known, this view does not go beyond hypothesis. Finally, it is held that the nervous system has a large, or even the chief share in the production of fever; the inflamed part acting through the nerves on the centre controlling the temperature of the body, which physiologists place in the medulla oblongata. But none of these theories is definitely established, and the manner, therefore, in which local inflammation produces fever is not yet perfectly understood. The degree in which local inflammations cause fever varies, and does not appear to depend wholly on the mass or the intensity of the inflammation, though both these conditions are partly concerned. Acute inflammations produce more fever than chronic, those of connective-tissue more than those of mucous surfaces, and, most of all, those which end in suppuration. In infective inflammations the fever is generally high, but not to be attributed to the local inflammation, being a concurrent effect of the same cause—the infective poison. Besides general fever, the special condition called *pyæmia*, in which other local inflammations result, may be a consequence of primary inflammation, but here, probably, some other factor is at work. See *Fever*, and *Pyæmia*.

Ætiology.—Most inflammations are caused by some injury—either mechanical, as by actual violence; or physical, as changes of temperature; or chemical, by powerfully acting substances, as acids, alkalies, and many more. A most important secondary factor is the condition of the body, whether under- or over-nourished, or in some other way wrong; and this may probably

be still more closely defined as the condition of the blood-vessels. Many parts of the body, as the skin and the stomach, are constantly exposed to injury, but do not become inflamed unless from some internal cause; and, therefore, a change of nutrition may be the apparent or immediate cause. It is also clear that certain inflammations, as herpes zoster, are determined by disturbance of the nerves; and it is very probable that similar nervous disturbances cause other local inflammations. Besides these there are certain specific causes, namely, infective or specific poisons, which, when introduced into the blood, produce local inflammations. Many local inflammations, external and internal, appear to arise spontaneously, neither irritation nor fault of nutrition being easily traced. Such are, for example, carbuncle and pneumonia. But in these, as in others, it is already probable that some infective cause is at work. It is also probable, and in some cases proved, that other inflammations which were at one time thought spontaneous, are really secondary, depending upon some previous local inflammation, even without what is called actual pyæmia. Thus the number of such apparently spontaneous inflammations is gradually lessening.

Treatment.—We shall divide this subject into the treatment of *directly accessible* (chiefly external) inflammations; and that of *indirectly accessible* (internal). Treatment will also differ according as the inflammation is acute or chronic; according to the stage, if acute; and also according to the constitution of the patient.

a. Directly accessible.—Directly accessible inflammation in an early stage may be treated by local blood-letting, and by astringents. The benefit of local blood-letting in an early stage is undoubted, and is probably due to its relieving the condition of stagnation, and permitting freer circulation of blood in the part. The type of astringents is *cold*. When the vascular disturbance, that is, hyperæmia, is great, and the general fever high, cold, produced either by ice or evaporation, is generally the best treatment. In the case of mechanical injuries, for instance, it may be regarded as an ascertained fact that if any injured part be kept cold during the period of reaction, the inflammation is less severe. When the condition of stasis, with exudation, is set up, the effect of cold is less marked; and if a temporary benefit is produced, the condition after the application of cold is stopped may be as bad as ever, or perhaps worse. The defect of cold as an antiphlogistic seems to be that, though it reduces hyperæmia, and if sufficiently intense actually checks inflammation, it does not remove the condition of the vascular wall on which stasis and the associated changes depend. Cold is also a powerful nervous sedative, and reduces the nervous irritability of inflamed parts. It is remarkable that an effect like that of cold is produced by solutions of certain *metallic salts*, especially those of lead, zinc, silver, and bismuth. These salts furnish the most certain and direct means of treating an inflammation in parts actually accessible to their action. Hence they are used in superficial inflammations of the mucous membranes, such as the digestive mucous membrane and the conjunctiva, and of the skin. Their use

is limited by the difficulty of bringing them in actual contact with deeper inflamed parts. But Mr. Hutchinson has shown that even in severe injuries the antiphlogistic effect of lead is quite equal to that of cold, if it can be made to pass deeply enough into the injured parts. These mineral (and vegetable astringents also) act more potently on the exudative processes of inflammation, than on the vascular disturbance. Hence their activity is most valuable when that of cold ends; and they have a striking effect on chronic inflammations which are unaffected by cold. Even *pressure* may be useful as an astringent, as we see in strapping a testicle or an inflamed joint. In applying all astringents, it is of the first importance to be sure that they actually arrive at the inflamed part. In applying ice to the chest for pneumonia or pericarditis, for instance, this result is very doubtful.

In the treatment of even acute inflammations, the precisely opposite application, that of *heat*, is sometimes valuable. Hot and cold have respectively always had their partisans, and have been, we think, needlessly opposed. If it were possible to apply a temperature high enough to kill leucocytes, it is probable that most inflammations might be suddenly brought to an end. Almost the only instance of this is the cure of a whitlow on the finger by plunging it into hot water; a treatment which would be more satisfactory if the necessary temperature were precisely fixed. Short of this, heat doubtless increases the activity of most inflammatory processes. But heat combined with *moisture* is the type of an *emollient*, by which the substance of inflamed tissues is relaxed, the blood-vessels dilated, the sense of tension and nervous irritation removed, and though exudation-processes are probably encouraged, the *mechanical* condition of stasis is relieved, and resolution is thus hastened. When pus is forming, there is little doubt that heat and moisture (in the form of poultices and fomentations), hasten the process, and increase the amount of pus formed; but the amount of pus is often of no great consequence, and it is more important to hasten the process. Thus it may be the right treatment for suppuration. When pus is once formed, the same treatment is useful in guiding it in the direction in which it is least hurtful. Finally, it may be beneficial to apply heat and moisture superficially, to relieve deep-seated organs, by stimulating the vascular and lymphatic circulation through the skin. Thus, in applying poultices for pneumonia we do not make the lung or even the pleura hotter, but relieve the overloaded blood-vessels and lymphatics.

Further, in treating all superficial inflammations we must guard against anything which increases the injury, such as movement, further irritation by the air or anything contained in the air. Thus, in some skin-diseases, as herpes zoster, secondary inflammation is prevented by an artificial covering of collodion. Antiseptic surgery shows that not the air, but something in the air, is to be feared, and if this is excluded much inflammation is prevented. The benefits of mechanical rest in treating injuries of the limbs need not be more than mentioned; nor that of physiological rest, wherever it can be obtained, in threatened or existing inflammation of any

active organ whatever—for example, the brain, the stomach, or the kidney.

In many acute inflammations, however, where the course of the inflammation is known, and we know we cannot absolutely stop the process, our best method may be merely to apply palliatives, that is, to adopt an *expectant method*.

Diet is also of great importance. There is little doubt that the intensity of all inflammations is lessened by greatly diminishing the food taken. In some acute inflammations, especially fevers, we may pursue a different system, with the view of saving the patient's strength; but it is possible that in the reaction against the starving process, feeding may be sometimes carried too far.

In the treatment of *chronic inflammation* in accessible parts, the first aim will be to check the exudation and cell-migration, that is, to bring the vascular wall into a healthy state. Here we find that metallic and vegetable astringents are most useful. But it may, with the same object, be well to draw more blood into the part, in order that the vascular wall may be better nourished. This is effected by *stimulants*, which are of well-known efficacy in chronic inflammation. These agents are for the most part the same as astringents, but in a more concentrated form—nitrate of silver, sulphate of copper, &c.; but also some aromatic substances, as tar, which is used in chronic inflammations of the skin, copalua for the urethra, &c. Again, it may happen that it is best to sweep the old tissue away, and allow new vessels to be formed, which will probably have healthier walls. This is effected by destructive *caustics*, as nitrate of silver, potassa fusa, chloride of zinc, or even the actual cautery.

In chronic inflammations, internal treatment is often of great service, as we shall presently show.

b. Indirectly accessible.—The treatment of indirectly accessible inflammations, or, what amounts to the same thing, the treatment by internal (general) methods even of directly accessible inflammations, is much less satisfactory than the local.

The first indication is to give the part actual rest, mechanical or physiological, the next, to consider if there is any way of reducing the intensity, either of the local reaction, or of the fever. Of such means the chief are general blood-letting; the general application of cold, and certain drugs called vascular depressants, such as mercurials, antimonials, purgatives, digitalis, aconite, quinine, and a number more.

Of *general blood-letting* we cannot say much here. There can be little doubt that it often lowers the energy of inflammatory processes in an early stage. If it has gone out of use, it is probably because the course of many diseases is now better known, and we do not expect to cut them short; because the list of infective diseases is enlarged; and because the benefits are supposed to be outweighed by the supposed drawbacks in diminishing the strength of the patient. Of *cold baths* we need only here say that they are far more potent in checking the condition of fever than in stopping local inflammation. Of *drugs* digitalis is supposed to act by depressing the heart's action; but in theory this is doubtful, and in practice we see little effect on organic inflam-

INFLAMMATION.

mations. *Aconite also has little local effect, but does modify the febrile state. Quinine is thought, on theoretical and experimental grounds, to check the emigration of leucocytes, and to kill organized leucocytes or germs resembling bacteria. The first belief is experimentally true if the drug is in a certain degree of concentration; but we have no safe means of introducing it, in this degree of concentration, into the blood. Alcohol even has been recommended as an antiphlogistic, on the ground that it lowers the temperature in health. But even this is not constant, and there is no good reason for thinking that it has this effect in fevers, still less that it checks the inflammatory process. If alcohol be given, it must be on other grounds. Salicylic acid, carbolic acid, and thymol are lauded as destroying fever-germs, but, as with quinine, we cannot get them into the blood in sufficient concentration, and if we could, it is probable that other more serious disturbances would be produced.

The conclusion must be that there is no one drug which is capable of controlling local processes of inflammation, though the resulting condition of fever may be modified.

The use of mercurials and antimonials seems to have been affected by the same considerations as blood-letting. The action formerly attributed to them is now doubted, and it is further thought they do harm in other ways. But no adequate explanation has been given of the difference in this respect between the practice of this and the last generation. Purgatives remain as a harmless, unquestionable, but not very potent antiphlogistic method.

In the general treatment of *chronic* inflammations we have more satisfactory principles. It is in cachectic persons, or persons with an inherited proclivity (perhaps not yet manifest) to cachectic diseases, that inflammations most tend to become chronic. Hence, the first rule is to improve the nutrition. Many patients with chronic inflammations get well at once when placed in good quarters, and on good food. Next in importance come nutrient tonics, of which cod-liver oil is the chief. There are few chronic inflammations in which it does not do good. Iron is very often valuable, and, if it fail or is contra-indicated, arsenic may be employed. In chronic inflammations of fibrous tissues, iodide of potassium has a real value, not easily explained. In treating other inflammations, either acute or chronic, there are many specific remedies, but these are remedies for the disease, not for its inflammatory features only. For this reason, we do not here speak of mercury, colchicum, salicylate of soda, and other agents.

Finally a most important means of treating indirectly accessible inflammations must be mentioned, namely that by *counter-irritants*, or setting up a rival inflammation. In order to relieve an inflammation, for instance, of the knee-joint, we produce a superficial inflammation of the skin. This is most used in chronic, but applies to some acute inflammations also. Various explanations have been given of the undoubted efficacy of this treatment. Some believe the action is transmitted through the nerves; others that blood is drawn away; others that the lymphatics are stimulated. The writer's belief is that in the most

marked cases of benefit from counter-irritation, there is a continuity of tissue between the inflamed organ and the part where the counter-irritant is applied, and that the action may sometimes consist in drawing away blood; but generally this is not possible, and the benefit results from setting up currents of plasma through the lymphatics and the connective-tissue spaces. It should be noted that in some inflammations, where œdema is a marked feature, simple puncture has an unquestionable efficacy which may perhaps be explained in the same way. The substances used for counter-irritation are either vesicants, such as cantharides or ammonia, or rubefacients, as mustard and iodine. Dry heat at different temperatures may produce the effect of either of these classes. When redness is produced on the skin, it does not follow that hyperæmia alone results. In fact the desquamation often shows that a low form of inflammation has been established. We have here endeavoured to give the principles only of the treatment of inflammation. For the treatment of inflammations of special parts, the articles on these subjects, as well as the articles on *BLOOD*, *ABSTRACTION OF*, *COUNTER-IRRITATION*; and *HEAT*, *Therapeutics of*, must be consulted.

J. F. PAYNE.

INFLATION (*infla*, I blow into).—A term applied, therapeutically, to the method of blowing air or gas into any hollow space. It is employed particularly in connection with the lungs in the process of artificial respiration (*see* *ARTIFICIAL RESPIRATION*). It is also used for the purpose of dilating the bowel in cases of obstruction (*see* *INTESTINAL OBSTRUCTION*). The term inflation was formerly used, pathologically, as a synonym for emphysema of the lungs, but is now more strictly limited to the condition in which the alveoli are temporarily distended with air, from any obstruction in the air-passages. *See* *LUNGS*, *Emphysema of*.

INFLUENZA—*SYNON.* Epidemic Catarrh; Fr. *Grippe*, Ger. *Influenza*, *Epidemischer Schnupfen*.

The term Influenza is said to have been first introduced in 1741, when the disease was prevailing in the North of Italy, and it has been generally adopted in this country, though the more scientific term—Epidemic Catarrhal Fever—is often used in systematic works.

DEFINITION—This disease is not to be regarded as simply an unusually prevalent common catarrh, but must be considered as a specific affection, which appears occasionally over wide districts, and at or about the same time; is characterised by marked febrile symptoms; is often attended by serious complications; and causes great and prolonged prostration of strength.

OCCURRENCE—Various epidemics of influenza are on record from the middle ages down to more recent times, and those which have occurred in the last and present centuries have been fully described. The disease is reported to have prevailed in 1729, 1732-33, 1737, 1742, 1758, 1762, 1767, 1775, and 1782, and in 1803, 1833, 1827, and 1847. The following account is chiefly founded upon the disease as it prevailed

is limited by the difficulty of bringing them in actual contact with deeper inflamed parts. But Mr. Hutchinson has shown that even in severe injuries the antiplogistic effect of lead is quite equal to that of cold, if it can be made to pass deeply enough into the injured parts. These mineral (and vegetable astringents also) act more potently on the exudative processes of inflammation, than on the vascular disturbance. Hence their activity is most valuable when that of cold ends; and they have a striking effect on chronic inflammations which are unaffected by cold. Even pressure may be useful as an astringent, as we see in strapping a testicle or an inflamed joint. In applying all astringents, it is of the first importance to be sure that they actually arrive at the inflamed part. In applying ice to the chest for pneumonia or pericarditis, for instance, this result is very doubtful.

In the treatment of even acute inflammations, the precisely opposite application, that of *heat*, is sometimes valuable. Hot and cold have respectively always had their partisans, and have been, we think, needlessly opposed. If it were possible to apply a temperature high enough to kill leucocytes, it is probable that most inflammations might be suddenly brought to an end. Almost the only instance of this is the cure of a whitlow on the finger by plunging it into hot water; a treatment which would be more satisfactory if the necessary temperature were precisely fixed. Short of this, heat doubtless increases the activity of most inflammatory processes. But heat combined with *moisture* is the type of an *emollient*, by which the substance of inflamed tissues is relaxed, the blood-vessels dilated, the sense of tension and nervous irritation removed, and though exudation-processes are probably encouraged, the *mechanical* condition of stasis is relieved, and resolution is thus hastened. When pus is forming, there is little doubt that heat and moisture (in the form of poultices and fomentations), hasten the process, and increase the amount of pus formed; but the amount of pus is often of no great consequence, and it is more important to hasten the process. Thus it may be the right treatment for suppuration. When pus is once formed, the same treatment is useful in guiding it in the direction in which it is least hurtful. Finally, it may be beneficial to apply heat and moisture superficially, to relieve deep-seated organs, by stimulating the vascular and lymphatic circulation through the skin. Thus, in applying poultices for pneumonia we do not make the lung or even the pleura hotter, but relieve the overloaded blood-vessels and lymphatics.

Further, in treating all superficial inflammations we must guard against anything which increases the injury, such as movement, further irritation by the air or anything contained in the air. Thus, in some skin-diseases, as herpes zoster, secondary inflammation is prevented by an artificial covering of collodion. Antiseptic surgery shows that not the air, but something in the air, is to be feared, and if this is excluded much inflammation is prevented. The benefits of mechanical rest in treating injuries of the limbs need not be more than mentioned; nor that of physiological rest, wherever it can be obtained, in threatened or existing inflammation of any

active organ whatever—for example, the brain, the stomach, or the kidney.

In many acute inflammations, however, where the course of the inflammation is known, and we know we cannot absolutely stop the process, our best method may be merely to apply palliatives, that is, to adopt an *expectant method*.

Diet is also of great importance. There is little doubt that the intensity of all inflammations is lessened by greatly diminishing the food taken. In some acute inflammations, especially fevers, we may pursue a different system, with the view of saving the patient's strength; but it is possible that in the reaction against the starving process, feeding may be sometimes carried too far.

In the treatment of *chronic inflammation* in accessible parts, the first aim will be to check the exudation and cell-migration, that is, to bring the vascular wall into a healthy state. Here we find that metallic and vegetable astringents are most useful. But it may, with the same object, be well to draw more blood into the part, in order that the vascular wall may be better nourished. This is effected by *stimulants*, which are of well-known efficacy in chronic inflammation. These agents are for the most part the same as astringents, but in a more concentrated form—nitrate of silver, sulphate of copper, &c., but also some aromatic substances, as tar, which is used in chronic inflammations of the skin, copalua for the urethra, &c. Again, it may happen that it is best to sweep the old tissue away, and allow new vessels to be formed, which will probably have healthier walls. This is effected by destructive *cauteries*, as nitrate of silver, potassa fusa, chloride of zinc, or even the actual cautery.

In chronic inflammations, internal treatment is often of great service, as we shall presently show.

b. Indirectly accessible.—The treatment of indirectly accessible inflammations, or, what amounts to the same thing, the treatment by internal (general) methods even of directly accessible inflammations, is much less satisfactory than the local.

The first indication is to give the part actual rest, mechanical or physiological; the next, to consider if there is any way of reducing the intensity, either of the local reaction, or of the fever. Of such means the chief are general blood-letting; the general application of cold; and certain drugs called vascular depressants, such as mercurials, antimonials, purgatives, digitalis, acetics, quinine, and a number more.

Of *general blood-letting* we cannot say much here. There can be little doubt that it often lowers the energy of inflammatory processes in an early stage. If it has gone out of use, it is probably because the course of many diseases is now better known, and we do not expect to cut them short; because the list of infective diseases is enlarged; and because the benefits are supposed to be outweighed by the supposed drawbacks in diminishing the strength of the patient. Of *cold baths* we need only here say that they are far more potent in checking the condition of fever, than in stopping local inflammation. Of *drugs*, digitalis is supposed to act by depressing the heart's action; but in theory this is doubtful, and in practice we see little effect on organic inflam-

mations. Aconite also has little local effect, but does modify the febrile state. Quinine is thought, on theoretical and experimental grounds, to check the emigration of leucocytes, and to kill organized bodies or germs resembling bacteria. The first belief is experimentally true if the drug is in a certain degree of concentration; but we have no safe means of introducing it, in this degree of concentration, into the blood. Alcohol even has been recommended as an antiphlogistic, on the ground that it lowers the temperature in health. But even this is not constant, and there is no good reason for thinking that it has this effect in fevers, still less that it checks the inflammatory process. If alcohol be given, it must be on other grounds. Salicylic acid, carbolic acid, and thymol are lauded as destroying fever-germs, but, as with quinine, we cannot get them into the blood in sufficient concentration, and if we could, it is probable that other more serious disturbances would be produced.

The conclusion must be that there is no one drug which is capable of controlling local processes of inflammation, though the resulting condition of fever may be modified.

The use of mercurials and antimonials seems to have been affected by the same considerations as blood-letting. The action formerly attributed to them is now doubted, and it is further thought they do harm in other ways. But no adequate explanation has been given of the difference in this respect between the practice of this and the last generation. Purgatives remain as a harmless, unquestionable, but not very potent antiphlogistic method.

In the general treatment of *chronic* inflammations we have more satisfactory principles. It is in cachectic persons, or persons with an inherited proclivity (perhaps not yet manifest) to cachectic diseases, that inflammations most tend to become chronic. Hence, the first rule is to improve the nutrition. Many patients with chronic inflammations get well at once when placed in good quarters, and on good food. Next in importance come nutrient tonics, of which cod-liver oil is the chief. There are few chronic inflammations in which it does not do good. Iron is very often valuable, and, if it fail or is contra-indicated, arsenic may be employed. In chronic inflammations of fibrous tissues, iodide of potassium has a real value, not easily explained. In treating other inflammations, either acute or chronic, there are many specific remedies, but these are remedies for the disease, not for its inflammatory features only. For this reason, we do not here speak of mercury, colchicum, salicylate of soda, and other agents.

Finally a most important means of treating indirectly accessible inflammations must be mentioned, namely that by *counter-irritants*, or setting up a rival inflammation. In order to relieve an inflammation, for instance, of the knee-joint, we produce a superficial inflammation of the skin. This is most used in chronic, but applies to some acute inflammations also. Various explanations have been given of the undoubted efficacy of this treatment. Some believe the action is transmitted through the nerves; others that blood is drawn away, others that the lymphatics are stimulated. The writer's belief is that in the most

marked cases of benefit from counter-irritation, there is a continuity of tissue between the inflamed organ and the part where the counter-irritant is applied, and that the action may sometimes consist in drawing away blood; but generally this is not possible, and the benefit results from setting up currents of plasma through the lymphatics and the connective-tissue spaces. It should be noted that in some inflammations, where œdema is a marked feature, simple puncture has an unquestionable efficacy which may perhaps be explained in the same way. The substances used for counter-irritation are either vesicants, such as cantharides or ammonia, or rubefacients, as mustard and iodine. Dry heat at different temperatures may produce the effect of either of these classes. When redness is produced on the skin, it does not follow that hyperæmia alone results. In fact the desquamation often shows that a low form of inflammation has been established. We have here endeavoured to give the principles only of the treatment of inflammation. For the treatment of inflammations of special parts, the articles on these subjects, as well as the articles on BLOOD, ABSTRACTION OF, COUNTER-IRRITATION; and HEAT, Therapeutics of, must be consulted.

J. F. PAYNE.

INFLATION (*infla*, I blow into).—A term applied, therapeutically, to the method of blowing air or gas into any hollow space. It is employed particularly in connection with the lungs in the process of artificial respiration (*see* ARTIFICIAL RESPIRATION). It is also used for the purpose of dilating the bowel in cases of obstruction (*see* INTESTINAL OBSTRUCTION). The term inflation was formerly used, pathologically, as a synonym for emphysema of the lungs, but is now more strictly limited to the condition in which the alveoli are temporarily distended with air, from any obstruction in the air-passages. *See* LUNGS, Emphysema of.

INFLUENZA—SYNON. Epidemic Catarrh; Fr. *Grippe*, Ger. *Influenza*, *Epidemischer Schnupfenfieber*.

The term Influenza is said to have been first introduced in 1741, when the disease was prevailing in the North of Italy, and it has been generally adopted in this country, though the more scientific term—Epidemic Catarrhal Fever—is often used in systematic works.

DEFINITION—This disease is not to be regarded as simply an unusually prevalent common catarrh, but must be considered as a specific affection, which appears occasionally over wide districts, and at or about the same time; is characterised by marked febrile symptoms, is often attended by serious complications, and causes great and prolonged prostration of strength.

OCCURRENCE—Various epidemics of influenza are on record from the middle ages down to more recent times, and those which have occurred in the last and present centuries have been fully described. The disease is reported to have prevailed in 1729, 1732-33, 1737, 1742, 1758, 1782, 1767, 1775, and 1782, and in 1803, 1833, 1827, and 1847. The following account is chiefly founded upon the disease as it prevailed

in 1817, but the description given of its peculiarities corresponds with the accounts of previous epidemics.

The disease may be described as assuming three distinct forms:—

1st. That in which it is *simple*, or unattended with any serious complication.

2nd. When it is *complicated* by serious affection of the aërial mucous membrane, and especially with bronchitis and pneumonia, and

3rd. When the *disorder of the digestive organs*, which generally exists to some degree in the disease, becomes a more prominent character, while there are marked rheumatic symptoms, and a tendency to assume a remittent form.

The description would also be imperfect without reference being made to the *modifying influence* which the epidemic exerts *over other diseases* prevailing at the same time, and especially over the specific fevers.

1. **Simple Catarrhal Fever—Symptoms.**—In this form of the disease the attack is most commonly sudden. The patient experiences a sense of cold down the back and between the shoulders, lapsing into general chilliness or complete rigors, and succeeded by flushes of heat and dryness of the skin, pain in the head, chest, and extremities, and prostration of strength. Generally these symptoms follow some exposure to cold and damp, but occasionally they appear without being traceable to any immediately exciting cause, and more rarely the attack comes on gradually, with a general feeling of indisposition of two or three days' duration.

At first there is dryness of the nostrils and soreness of the throat, with a sense of tightness or constriction of the chest, and a dry, hard cough. As the disease advances, copious defluxion from the nostrils takes place; the throat is often seriously affected, and the cough is more frequent. The expectoration is at first scanty, and consists of a pale glairy fluid, but at a later period there is more copious discharge of opaque mucus. At the same time some degree of difficulty of breathing and soreness at the chest are experienced. The respiration is in most instances accelerated; and, on auscultation, the inspiratory sounds are dry and harsh, especially in the posterior and inferior parts of the chest, and sibilant and sonorous rhonchi may be audible on forced inspiration. In some cases no marked sounds are heard, but the vesicular murmur is very indistinct. A sense of chilliness, alternating with flushes of heat, is a general symptom throughout the progress of the attack, and there is distressing headache, particularly in the forehead, across one or both eyebrows, as well as pain in the balls of the eyes. These symptoms often undergo considerable remission during the day, and become much increased in severity towards night. There is also commonly much mental depression, listlessness, inability for intellectual exertion, and nocturnal restlessness. The tongue is usually moist, and covered with a white creamy fur, but occasionally it is noticeably red at the tip and edges, and thickly coated with a white-lavender fur towards the centre and root; more rarely, and especially in the morning, it is dry. In the greater number of cases, entire loss of appetite, with some nausea, and a confined

state of the bowels, are present from the commencement; but occasionally diarrhœa is observed at an early period, and not unfrequently it comes on during the progress of the disease. Sense of weight, tenderness, and pain in the right hypochondrium are frequently experienced, and there is often some icteroid tinging of the conjunctivæ, or of the general complexion. The urine is scanty and high-coloured at first, but subsequently becomes more free, and deposits some sediment.

Prostration of strength is throughout one of the most marked and distressing features of the complaint, and there is a general feeling of soreness, with dull aching pains in the chest, back, and limbs. The pulse is but little varied in frequency, generally ranging from eighty to ninety, and rarely exceeding a hundred beats in the minute. Though occasionally full, it is uniformly very compressible, and, after the first day or two, feeble. The skin is seldom hot or very dry, or, if so, it is only at the commencement of the attack, and it soon becomes cool and moist, the complaint usually subsides with free perspiration.

The ordinary duration of the indisposition in this form of the epidemic may be stated at from three to five days in the milder cases, and from seven to ten in those of a more severe description. The disease, however, on its subsidence usually leaves the patient for some time much prostrated, and suffering from loss of appetite, inaptitude for bodily or mental exertion, and a troublesome cough. There is a great tendency to relapse.

Not unfrequently towards the termination of the attack the transient pains, which are troublesome during its course, increase in severity, and rheumatic affections of an obstinate and painful character supervene. These often assume a remittent or intermittent form, returning regularly at the same hour for several days in succession, and not unfrequently affecting one side of the head, or one eyebrow or eyelid, and occasionally the intercostal muscles of one side of the chest.

2. **Epidemic Catarrhal Fever with predominant Pulmonary Affection—Symptoms.** It has already been noticed that some amount of soreness of the throat, and unconsciousness or pain in the chest, with cough and expectoration and slight bronchitic signs, are observed in the cases of the epidemic which might be considered as assuming the simple form. Not unfrequently, however, the symptoms of affection of the aërial mucous membrane are more marked, there being decided quinsy, laryngeal symptoms, croup, bronchitis, or pneumonia. Of these, however, the most frequent and important are the bronchitic and pneumonic complications.

The bronchitis has especially the tendency to assume the acute capillary form. In cases of *acute capillary bronchitis* occurring as a complication of influenza, there is usually in the early stage increased frequency and some difficulty of breathing, constriction of the chest, and soreness or stiffness of the throat. The cough, though slight, is troublesome from its frequency. The expectoration, if there be any, is scanty and of a glairy character. The tongue is usually red at the tip and edges, and covered at the dorsum

with a creamy mucus or with a whitish-brown fur; occasionally it is morbidly red throughout. The pulse is accelerated, beating generally 110 to 112 or 116 in the minute, and occasionally more. The skin is not usually hot, except it be at the commencement of the attack, and if so it usually becomes cooler in two or three days. With these symptoms there are the marked prostration of strength, the severe frontal headache, the general soreness of the body, and the pain in the back and limbs, which characterise the ordinary cases of influenza.

When the chest is examined in this stage of the disease, the only morbid signs detected are a roughness of the inspiratory sound, particularly when a forced inspiration is drawn, some slight crepitation, audible more especially towards the lower part of each dorsal region, feebleness of the vesicular murmur, and perhaps slight sibilant rhonchus in front. The respiration is, however, quicker and shorter than natural, averaging 28, 32, or 40 in the minute; the dyspnoea is greater than is explained by the obvious physical signs, and most generally there is some lividity of the face.

In the second stage all these symptoms are much aggravated. The respiratory acts are performed quickly and imperfectly, the respirations in the minute varying from 30 to 40 or 50. The cheeks are much flushed, and the lips of a somewhat purple colour. Generally there is not acute pain in the chest, but rather a sense of constriction and soreness, the cough, though frequent and occurring in paroxysms, is not usually severe. The expectoration still continues scanty, and consists of small yellowish-white pellets, forming tenacious masses of a peculiar nodulated or butyriform form, very much resembling, when floating in water, fragments of some of the large oolitic limestones. The tongue is mostly covered with a thick whitish-brown fur, and somewhat dry and often red at the tip and edges; or morbidly red and glazed. The pulse is much accelerated, beating 120, 130, or 140 times in the minute, but it is generally small and very compressible. In some instances, after being low and feeble at the outset of the disease, it acquires a more sthenic character in the second stage. The skin is rarely dry, or much above the natural temperature; and the hands and feet are generally cool. The skin of the extremities is also much congested, so that when blanched by pressure, the colour does not readily return. The prostration of strength also becomes greater; and there is much headache, and often transient delirium, especially during the night. On percussion, the chest does not present any marked alteration of resonance, unless there exists some other disease of the lung, and on auscultation, crepitation of a more or less fine character is audible with the inspiration, first in the inferior part of one or both dorsal regions, then spreading rapidly higher up in the back and toward the bases of the lungs in front, whilst sibilant rhonchus is heard in other parts of the chest.

The third stage of the disease is marked by the dyspnoea becoming so severe that the patients are compelled to sit constantly upright in bed, or to lean forwards, resting on their arms and elbows,

whilst at intervals the respiration becomes very laborious. The lividity of the cheeks, lips, and hands is increased; the eyes become prominent; and the expression of countenance is extremely anxious. The cough is frequent, and of a short abortive character, giving the impression of viscid secretion in the lung, which the patient has not power to expectorate, whilst it is aggravated by paroxysms, which cause pain in the head, and increased lividity. The sputum now becomes large in quantity, it is of a greenish-yellow colour, very viscid, contains little air, and is occasionally streaked with blood. The respirations are very frequent, 50 to 60, or even more, and expiration is very laboured and prolonged. The pulse is very feeble, and either extremely quick—140, 150, or 160 in the minute—or intermittent, so as to number only 100 or 120 beats. The tongue is covered with a thick yellowish-white or brown fur, and is generally dry, sores also form upon the teeth. The general surface of the body becomes cool and bathed in perspiration; and the hands and feet decidedly cold. The delirium is more constant; with the decaying strength the cough declines; the expectoration ceases or becomes slight; and the patient sinks.

With the progress of the disease the physical signs change. The chest in front yields a uniformly clear sound on percussion, while behind there is a general impairment of the resonance. The crepitation gradually extends over larger portions of the lungs, being of a finer character in the parts more recently involved; giving place to subcrepitant and mucous rhonchi in the situation in which it was first heard, and finally becoming of a gurgling character in the neighbourhood of the larger bronchial tubes. The subcrepitant rhonchus also towards the end of the attack is heard with the expiration as well as with the inspiration, and if there is some local condensation, bronchial respiration may be developed.

In the cases which terminate favourably, the amendment is marked by the respiration becoming less hurried and laborious; by the expression of countenance being less anxious, and the face less livid, and by the prostration of strength decreasing. The pulse becomes less frequent, the cough less severe, and the sputum less viscid—more of a mucopurulent character with a tendency to form a homogeneous mass, containing large air-bells. At a later period it becomes thinner, and declines in amount. The mucous and subcrepitant rhonchi are replaced by finer sounds, and the space over which the morbid signs are heard diminishes—these disappearing first in the upper part of the chest, then at the front and sides, and lastly in the dorsal regions. The clearness of the sound on percussion on the front of the chest also passes away, and is often succeeded by a somewhat dull sound; and the respiratory sounds become indistinct. The convalescence is, however, generally protracted; the patient is liable to returns of dyspnoea at intervals; and the cough continues troublesome. After the subsidence of the pulmonary symptoms, the rheumatic pains, if previously present, may become aggravated, or may then first appear and become troublesome, affecting the head, face, &c.

interested muscles, and being aggravated towards night.

ANATOMICAL CHARACTER.—On examination after death, one of the peculiar features of this form of disease is the extremely inflated condition of the lungs, which in lieu of collapsing when the chest is laid open, in some cases protrude from the cavity. This condition is not limited to certain parts in which there are larger or smaller bullae, but consists in a general inflation of large portions of the lung. The mucous membrane of the bronchi is reddened, and the injection increases towards the smaller tubes, where the membrane may be intensely red and have a villous appearance. The lung-tissue in the cases proving fatal at an early period has a peculiar dry appearance, but in the later stages it is oedematous. There is also more or less lobular condensation, the condensed parts being depressed below the adjacent inflated tissue, and having a deep purple colour. At a later period the condensed tissue may soften from the presence of pus, and small cavities may be formed in this manner. The bronchial glands are enlarged and softened. The cavities of the heart, especially on the right side, are distended with firm and more or less decolourised coagula.

PROGNOSIS AND DURATION.—The cases of influenza complicated by acute capillary bronchitis are always very serious in their character, and when the disease occurs in persons who have before been out of health, and especially if there be any previous disease of the lungs or heart, or if the subjects be very young or elderly, they prove fatal in a large proportion of cases. The duration of the disease in the cases which prove fatal is from about ten to fourteen days, and when recovery occurs, the patient is ill from a fortnight to three weeks, or longer.

Pneumonia.—In the cases of pneumonia which were seen during the prevalence of the last epidemic of influenza, the disease was very generally combined with bronchitis, either affecting the larger or smaller tubes, yet the cases were less serious than those in which the disease assumed the form of acute capillary bronchitis alone. This is the more remarkable as they were more frequently combined with serious disorder of the abdominal organs, and with rheumatic symptoms, and were attended with great prostration of strength. Of the symptoms in these cases, cough is one of the most troublesome; the expectoration is peculiar, partaking both of the glassy, transparent, or opaque character of the sputum of bronchitis, and of the brownish viscid expectoration of pneumonia, with the usual small air-bells. In some cases, however, when there is great prostration, there may be no expectoration. Pain in the chest is generally experienced at the invasion of the disease, of a more or less severe character, but afterwards it is not present to any marked extent, or is only experienced when the patient has a severe paroxysm of coughing. The dyspnoea also is not severe, and there is not much lividity of the face, unless in cases in which there is also considerable bronchitis. The breathing is not usually very rapid, the respirations not exceeding 20 or 30 in the minute. The pulse also

is comparatively quiet, beating 80, 90, or 100, and it is usually soft and compressible, or decidedly small and weak. The skin, as in the other forms of influenza, is not generally hot or dry; or, if so at the commencement of the attack, it soon becomes cool and moist. The tongue has usually the whitish-brown covering which has before been described, and is not dry, but sometimes it does become dry and brown. There is often very marked disorder of the digestive organs—sickness and vomiting and diarrhoea; and usually some slight jaundiced tinge of the skin is observed. There is also not unfrequently some delirium and stupor of mind, and the prostration of strength is often extreme. On examining the chest, in addition to the signs of bronchitis, which are always present to a greater or less degree, there are the usual indications of pneumonia. At first fine crepitation is perceived in the seat of the disease, to this more or less marked dullness on percussion, bronchial respiration, and increased resonance of the voice and cough succeed, and these signs, though generally found in one or both dorsal regions, may be more widely diffused. Notwithstanding, however, the threatening character of the symptoms, it was observed in the epidemic of 1847 that the disease was not very fatal, and the signs of consolidation disappeared more readily than in most ordinary cases of pneumonia. The resolution was shown by the return of crepitation, though of a coarser character, in the seat of consolidation, and by the gradual diminution of the bronchial respiration, and of the dullness on percussion. After a time the natural vesicular breathing again became audible. The duration of the disease was very similar to that in the cases of acute capillary bronchitis. In this, as in the other forms of influenza, the convalescence was often very protracted, there was the same tendency to recurrence of the symptoms on any slight exciting cause, and the rheumatic pains often long continued to distress the patient.

3. Catarrhal Fever, complicated with gastro-intestinal affections and rheumatism, and of a remittent character.

It has already been stated that in the last epidemic of influenza, there were very generally present more or less marked symptoms of gastro-intestinal and hepatic disorder, and that rheumatic pains, having a more or less decidedly remittent character, were very usually observed. It has further been said that in the cases in which the pulmonary complication assumed the pneumonic form, these symptoms were generally more marked than in the cases of acute capillary bronchitis.

In some cases, however, the latter symptoms were, throughout, the predominant feature, and as similar observations have been made as to former epidemics, cases of this kind may fairly be regarded as constituting a special form of the disease.

In this form of the epidemic, nausea and sickness generally occurred at an early period of the attack, and often became very urgent symptoms. The matters vomited often had a bilious tinge; and there was generally a marked bilious tinge of the conjunctive and general surface of the body, amounting in some cases to decided jaun-

face. There was often diarrhoea; and sometimes blood was passed in the stools. The pains in the head, back, loins, and extremities, which are present with more or less severity in all forms of influenza, were from the first of a severe character, or increased with the progress of the disease till they constituted a predominant feature. The pain was usually most distressing in the head, especially in the forehead and in some cases was limited to one temple, one eyebrow, or one eyeball. This was generally of an intermittent or remittent character, coming on at night after more or less distinct remission during the day; and was attended with singing in the ears, distressing restlessness, agitation, and inability to sleep, whilst delirium generally increased during the exacerbation. In some cases it only amounted to a little excitement and incoherence, but in others it was so urgent as to require the employment of restraint to retain the patient in bed, and sometimes it continued without intermission for some hours. It was, however, remarkable how completely it subsided, as a rule, in the morning. With these symptoms there was usually much tremor of the extremities, and the eye was pale and glassy, though the pupil was frequently contracted.

Early in the attack the pulse was quick and feeble, and of a peculiarly vibratory character, though sometimes it was but little accelerated. At a later period it often became very rapid and feeble, or fell below the natural standard of frequency, being very soft and compressible, and occasionally intermittent. The tongue was at first moist, covered with the usual whity-brown fur, and red at the tip, subsequently it had a tendency to become dry. The breath had a peculiar, offensive, acid odour. Epistaxis occasionally occurred, and sometimes to an alarming amount. The skin was generally moist; and the perspiration had the usual sour rheumatic smell. The urine was at first scanty, but afterwards increased in quantity, and deposited much sediment of urates. Occasionally it was slightly albuminous.

With these symptoms there were evidences of some pulmonary disorder—bronchitis or pneumonia, and very frequently murmurs were heard at the heart, which were not, however, generally persistent.

After the exacerbations the sweating was often very profuse, so that in the morning the patient was found completely bathed in it, and the bedclothes were quite wet. The prostration of strength also was often extreme, so that the hands and feet became livid and cold, and the patient resembled a person in the algid stage of cholera.

Notwithstanding their severity, the cases of this third form of influenza generally did well, though the patients long suffered from the rheumatic symptoms, and only very slowly recovered their strength. As seen from the Registrar-General's reports, there was a great increase in the deaths from 'rheumatism' during the prevalence of the epidemic, which probably referred to cases of this kind.

4. **Modifying Influence of the Presence of Influenza on other Diseases.**—In all visitations of influenza of which we have detailed

accounts, the epidemic has been attended by an unusual prevalence of other forms of disease, and especially of the specific fevers—and the features of such diseases have been much modified by the epidemic influenza. To this rule the influenza of 1847 affords no exception. As shown by the reports of the deaths in London and the country generally, there was a great increase in the total mortality, this especially showed itself in the zymotic class of diseases, but obtained also as to diseases of the heart, brain, and digestive organs. An unusual number of deaths were recorded from 'typhus,' under which head were then included the fevers which we now discriminate into typhus, typhoid, and relapsing fever. Of all these forms of disease, cases occurred during the time, though the chief prevalence was apparently of typhoid and relapsing fever. The features of these diseases were generally so much modified by the epidemic influenza, and they were so constantly attended by pulmonary complications, that it was often difficult to decide whether any given case was to be regarded as a case of specific fever or of influenza. Various forms of local disease were also prevalent at the time, both as distinct affections, and as complications of specific fever, such as diphtheria, parotitis, otitis, stomatitis, and quinsy, with erysipelas, abscesses, &c., and these were often attended by great prostration of strength, and added greatly to the danger of the various other forms of disease with which they were combined.

PATHOLOGY.—Every phenomenon of influenza points conclusively to the influence of some powerful depressing agent, operating on the nervous system, or entering the blood. The sudden seizure of a large proportion of cases; the extreme prostration of strength from the commencement, and to a degree disproportioned to the amount of local disturbance; the symptoms of disorder of all organs, and especially of the cerebro-spinal system, and the debility which so often succeeds even simple cases of the disease, can on no other supposition be explained. It seems probable also that the affection of the respiratory mucous membrane may be due to the morbid influence, whatever it may be, operating more specifically upon it, but it is extremely difficult to offer even a probable suggestion as to the nature of that influence. The almost simultaneous outbreak of the epidemic in places widely apart, the seizure of a large proportion of the population of a town or district within the course of a few hours; and the sudden illness of individuals or bodies of men visiting a locality where influenza is, or has very recently been, prevailing, and previous to direct intercourse with any persons actually suffering—are all circumstances opposed to the notion of the disease being dependent on infection in the ordinarily understood sense; and might seem to point to the operation of atmospheric influence as the cause. The conditions, however, under which the disease has presented itself in different epidemics, render such an explanation impossible. It has travelled over districts without reference to season or climate, and has prevailed in the same locality in all seasons and in almost every variety of weather. It is true that it has often broken out,

after great meteorological changes, as in the last two epidemics after sudden and remarkable falls from a comparatively high to a very low temperature; but, on the other hand, epidemics have arisen under other circumstances, and such alternations of temperature frequently occur without the occurrence of an epidemic of influenza. The disease has also broken out at the same time at different places in which the same atmospheric conditions did not exist, so that the operation of the sudden change can scarcely be regarded as acting even as an exciting cause. There can, however, be no doubt that the more common predispositions to disease, such as defective drainage, overcrowding, impure air, deficient clothing, and insufficient or unwholesome food, powerfully conduce to the prevalence and fatality of the epidemic.

TREATMENT.—Of the treatment of the simpler forms of influenza it is not necessary to say much. The patient should be confined to bed, have a footbath, take some form of diaphoretic medicine; and be allowed a mild, unstimulating diet. If the cough becomes troublesome, or if there be pains in the chest, sinapisms may be applied, and some anodyne may be added to the medicine; and for the relief of the subsequent debility, stimulants, tonics, and a nutritious diet may be enjoined. In the cases complicated with pulmonary affections, the same measures may be used, in combination with expectorants and anodynes; and more decided counter-irritation may be applied to the chest. When there is very copious secretion, and the patient cannot expectorate freely, the greatest benefit is often derived from the use of emetics, and they may be employed with advantage in cases in which the patient's strength is too much depressed to allow of nauseating doses of medicine being given. To the use of emetics, the stimulating expectorants—squills, ammonia, &c.—should succeed. For the relief of the cases in which there is nausea and sickness or vomiting, effluents with morphia, or hydrocyanic acid, may be given. When there is more or less jaundice, small doses of calomel or grey powder, in combination with Dover's powder, are very beneficial; and when there is diarrhoea the Dover's powder or decided astringents—such as acetate of lead, or tannic acid—may be employed. When the rheumatic symptoms are severe, the greatest relief is obtained by the administration of small doses of colchicum with carbonate of potash and opiate; and when the prostration of strength is great, ammonia, in combination with bark, should be given. In the cases in which there is a decided tendency to remissions and exacerbations, bark also may be prescribed, or, in the more severe cases, quinine; and quinine and other tonics should be freely given during convalescence.

In all cases of influenza all depressing treatment should be avoided. The cases do not require it, and the patients are too much prostrated to admit of its employment. In all the different forms of influenza it is necessary to administer support very freely, and sooner or later to exhibit stimulants. In the cases in which there is pulmonary or other local complication, the strength becomes more rapidly and more

seriously depressed, and stimulants and support are still more urgently needed; and indeed it is necessary to have recourse to them at an earlier period, to exhibit them more freely, and to persevere in their use for a longer period in such affections, when occurring during an attack of influenza than when arising as idiopathic diseases. In the management also of the other forms of febrile affections which are seen during an epidemic of influenza, a more restorative and stimulating treatment is required than under ordinary circumstances, for all such diseases partake of the peculiarly æsthetic type of the epidemic.

THOMAS B. PRACOCKE.

INHALATION. *Ætiology of.*—See DISEASE, Causes of.

INHALATIONS, Therapeutic Uses of (*inhale*, I breathe in).—Inhalation is a method of applying remedial agents to the respiratory tract, whereby these substances in a gaseous or atomized form are brought into contact with the mucous membrane of the nose, mouth, pharynx, larynx, and bronchi, and may even penetrate to the epithelium of the air-cells. Inhalation dates from the days of Hippocrates and Galen, and has been more or less in vogue in all ages, but only lately has it been proved that the inhaled material passed through the finest ramifications of the bronchi into the pulmonary alveoli, and in some instances became absorbed by the capillaries, thus entering the general circulation. The examination of the lungs of colliers, grinders, and others engaged in dusty occupations has shown that the inhaled dust can be detected in the lung-tissue, where it induces chronic pneumonia. The experiments at the Académie de Médecine proved that medical sprays are equally penetrating.

METHODS.—The modes of inhalation vary with the drug used, depending mainly on the temperature at which it volatilizes, and also on the medicinal effects aimed at.

Chloroform, ether, bichloride of methylene, and nitrate of amyl evaporate at ordinary temperatures, and only need to be diluted with air to be safely inhaled. Calomel and sulphur are sublimed at high temperatures in special apparatuses, but the majority of drugs are best vaporized through the medium of hot water or steam, or reduced to fine spray by passing compressed air through their solutions.

Many forms of inhaler are in use, but in selecting one for warm inhalations the requisites are:—(1) that it can be used without difficulty by the patient; (2) that a temperature of 130° to 150° F. can be steadily maintained, (3) that the steam be thoroughly impregnated with the medicament; and (4) that the inhaling tube be fitted to the nostrils as well as to the mouth, so as to ensure a sufficient supply of the inhaled vapour. When no inhaler is at hand, a jug with a wide mouth and half filled with hot water may be used, a towel being placed round between the mouth and nose of the patient and the opening of the jug, to prevent the escape of the vapour into the air.

VARIETIES AND USES.—Inhalations are employed chiefly in diseases of the pharynx, larynx, and air-passages, and may be classed as *sedative*, *stimulant*, and *antisepctic*.

Sedative.—Steam is soothing to the throat,

when this part is dry, inflamed, or irritable. In incipient laryngitis and croup, as well as in irritable bronchitis, the inspiration of steam from specially arranged kettles is very grateful, the moist vapour promoting secretion and expectoration.

Jets of steam are used in hospitals and bath establishments as vehicles for the inhaled drugs, and are directed into the patient's mouth.

As sedatives the vapor conii and the vapor acidi hydrocyanici are recommended in cases of laryngeal or pulmonary irritation. A sedative inhalation made of equal parts of chloroform and rectified spirit—of which one teaspoonful may be added to a pint of water, at 60° to 100° F.—is much commended in hay-fever and laryngeal spasm. A combination of chloroform and conium, in the proportion of 15 minims of the former to 1 drachm of the succus conii, in half a pint of boiling water, is useful in phthisis and some forms of asthma.

Stimulant.—Stimulating moist inhalations can be prepared with various volatile oils. Oils of pine and of cubebs are useful stimulants in cases where there is much secretion from the throat and air-tubes. Thus 2 drachms of oil of pine or oil of cubebs may be mixed with 60 grains of light carbonate of magnesia in 3 ounces of water; and of this mixture 1 drachm may be used in a pint of water at each inhalation. One drachm of the compound tincture of benzoin, in half a pint of hot water, is often useful in chronic bronchitis and laryngitis. Oil of turpentine or of pinus silvestris (1 drachm to the half-pint of hot water) makes excellent stimulant inhalations in cases of dilated bronchi.

Antiseptic.—Antiseptic inhalations are used where the object is to correct a fetid secretion, as well as to stimulate the secreting membrane to fresh action. In fetid bronchorrhoea, in gangrene of the lung, in fetid abscess, and in pyopneumothorax, benefit is derived from the vapor creasoti, the vapor iodi, or from glycerine of carbolic acid (from 2 to 3 drachms to the pint of boiling water), or again from oil of thymol, prepared like the other essential oil vapours, with light magnesia and hot water (10 grains to the 3 ounces). The fumes of nitre paper are employed as inhalations in cases of pure spasmodic asthma uncomplicated with bronchitis. The paper—prepared by soaking white blotting-paper in solution of nitrate of potash—is sometimes washed over with tincture of benzoin, and this, in certain cases, may be an improvement; but in ordinary forms of asthma the nitre paper (30 or 40 grains of nitrate of potash to 1 ounce of water to form the solution for soaking the paper) burnt till the patient is enveloped in smoke, will usually relieve the asthmatic paroxysm. The fume of a grain of powdered opium volatilised on hot metal has been praised as a remedy to cut short nasal catarrh, as well as smoking solid opium in the Chinese fashion through a pipe, in spasmodic asthma. Cigarettes and pistules containing stramonium and other antispasmodics, are sometimes used with benefit.

Atomised inhalations of spray have of late years come into deserved repute as valuable aids to the treatment of chronic diseases of the throat and lungs. The principle of the hand ball and

steam-spray atomisers is, that if two capillary tubes are placed at a certain angle to each other, one dipping into a fluid, while through the other a stream of air is driven by heat or compression, a vacuum is formed in the first, causing the liquid to pass out in the form of fine spray. In using these instruments, the operator should seek to blow the spray into the patient's throat at the time when an inspiration is being taken, as thus the spray will obtain a free entrance through the larynx into the trachea. It is doubtful if much spray enters the air-tubes; some certainly does, as has been stated above, but the cold sprays do not appear to afford so much relief to affections of the lungs as the warm inhalations. In cases of tumidity of the larynx, a spray containing 10 grains of alum to 1 ounce of distilled water may be used. In place of alum, 2 grains of sulphate of iron, 5 grains of sulphate of zinc, or 5 grains of dry chloride of iron, in 1 ounce of water, may be employed. For antiseptic purposes, 5 minims of sulphurous acid, or 1 minim of carbolic acid, to 1 ounce of water, or a like quantity of liquor iodi may be used. In putrid sore-throat and diphtheria the writer has seen excellent results from iodine, either inhaled in vapour or applied in solution. Three and a half drachms of lactic acid in 10 ounces of water form a solution which, thrown as spray into the throat, is of use in diphtheria, it seems to dissolve the exudation. As a styptic and hæmostatic spray 50 to 200 grains of tannic acid are employed, dissolved in 10 ounces of water, but for relaxed throat a weaker solution is useful. For sedative purposes a solution of bromide of ammonium, or one containing half a grain of acetate of morphia to 1 ounce of water, may be employed. Diluted speucuanha wine spray is said to be very efficacious in relieving the dyspnoea of chronic bronchitis and emphysema. This spray in a few instances may induce vomiting, but this accident may be obviated by diluting the wine with a considerable proportion of water. At the Continental spas it is usual to medicate large chambers by means of sprays and vapours, in which patients can sit for hours breathing the artificial atmospheres, and in this way various mineral waters, such as those of La Bourboule, Aix-les-Bains, and Cauterets are locally applied.

JOHN C. THOROWGOOD.

INJECTION (*injection*, I throw in).—**SYNON.** *Fr. Injection, Ger. Einspritzung.*

DEFINITION.—Injection is the act of introducing a fluid into any part of the body, by means of a syringe or similar apparatus. The word is also employed to designate the fluid so introduced.

VARIETIES.—Injections are chiefly used in the treatment of disease, but reference must also be made to the method as it is practised by anatomists for the preservation of 'subjects' for dissection, and for the purpose of filling the blood-vessels, lymphatics, ducts, cavities, spurs, &c. preparatory to microscopical examination.

The therapeutical application of injections comprehends the following measures:—

1. *Hypodermic or subcutaneous injection*, in which the fluid is injected under the skin. *See* **HYPODERMIC INJECTION.**
2. *Injections into the natural canals or open*

cavities of the body; for example, the external ear, the Eustachian tube, the nose, the nasal duct, the stomach, the rectum (see ENEMA), the urethra, the bladder, and the vagina and uterus. The various forms of injections just indicated will be found fully discussed under the diseases of the several organs.

3. Injections into *shut sacs*, normal or morbid, such as the tunica vaginalis, the serous cavities, the synovial cavities, the sheaths of tendons, and cysts and chronic abscesses. The fluids used in this class of injections are generally stimulant, such as a solution of iodine. See HYDROCELE.

4. *Intravenous* injections, the fluid introduced into the circulation being either blood (transfusion), milk, or some kind of nutritive solution. See TRANSFUSION. J. MITCHELL BRUCE

INOCULATION (*in*, into, and *oculus*, a bud, a graft).—As usually understood, inoculation is either an operative procedure or an accidental occurrence, by means of which morbid materials are brought into direct contact with the minute vessels of the skin or of a mucous membrane, or with those of the subcutaneous or submucous tissue, so that they are readily and speedily absorbed, the result being that they originate certain definite and specific diseases, varying with the nature of the material employed. In short, inoculation, as commonly practised or observed, is a mode by which the contagia of certain specific diseases are conveyed from one animal or individual to another, and some of these affections can only be thus transmitted, while others are capable of being communicated in other ways, but in this way most effectually and with the greatest degree of certainty. The most familiar examples of diseases thus transmitted are *vaccina*, small-pox, syphilis, and hydrophobia. It need hardly be mentioned that *vaccina* can only be conveyed by inoculation, and it is for the purpose of inducing this disease that the method is ordinarily intentionally practised, so that the terms *vaccination* and *inoculation* have come to be popularly regarded as synonymous (see VACCINATION). Under certain exceptional circumstances inoculation of the contagious matter of syphilis, small-pox, or anthrax is employed, with the deliberate purpose of originating these affections (see SMALL-POX; SYPHILIS; and PUSTULE, MALIGNANT). This plan has also been practised of late years in experimental pathology, by which the effects of the inoculation of septic liquids upon the system have been demonstrated; while it has also been shown that the introduction of certain solid morbid products in this way may originate an infective process, leading to definite pathological results. See CONTAGION.

With regard to the modes by which inoculation is effected, it need only be said here that when it is practised as an operation, the material is usually introduced into the subcutaneous or submucous tissues, by means of a lancet or other pointed instrument. Sometimes the surface of the skin is merely scarified, so that the epidermis is more or less destroyed; or this is removed by some blistering agent, and the contagious substance then applied to the exposed cutis. Accidental inoculation may take place in

connection with any abrasion, wound or ulcer on the skin or on a mucous surface, or by the bites of animals, as in the case of hydrophobia.

FREDERICK T. ROBERTS.

INSANITY.—SYNON.: *Fr. Folie*, Ger. *Geisteskrankheit*, *Geistesstörung*.

Insanity is popularly known as disorder of mind. As physicians, we know it to be disorder of the highest organs of the nervous system which unite in the performance of that function recognised and spoken of as mind. There can be no disorder of mind without disorder of brain: as physiologists and pathologists we have to study and treat the latter, and for this reason the legislature enacts that certificates of insanity shall be given by medical men, and by them alone, and that to their care shall be committed those who are insane.

As a preparation, then, for the study of insane mind, the learner ought to acquire a knowledge of healthy mind—the healthy function of a healthy brain. He must know what are the structures which combine to make up that which we call the cerebrum, and contribute to its healthy working, and must trace the growth and development of this working from the earliest days of infancy to the time of adult life. He will perceive that the growth of mental function is as gradual as that of bodily power, that in some it may be more rapid than in others, like that of the body, that it may be arrested in its development, or stunted and deformed, and that it may by imperfection of the organs, as blindness or deafness, be impeded or stopped. In all particulars it will be found subject to the laws which regulate the growth of the body generally.

Before examining brain-function, it will be necessary to become acquainted with the various structures which form the cerebrum. The brain of man, and indeed of all vertebrates, is made up of nerve-cells and nerve-fibres; of a substance or *stroma* in which the cells are imbedded, called neuroglia, and of blood-vessels and lymphatics. The nerve-cells are gathered into convolutions or *centres*, and by means of the nerve-fibres communicate with the organs of special sense, with the sensory ganglia and spinal cord, with each other, and with the convolutions of the other hemisphere. Modern science is endeavouring to throw light upon the nature and uses of these convolutions. The seats of the highest intelligence, they at the same time appear to be centres of voluntary motion, and of the outward manifestation of intellectual action.

Concerning the physiology of the blood-supply of the brain there is still great doubt and controversy. Anatomically we know that from the internal carotid and vertebral arteries, combining in the circle of Willis, there pass to the brain-substance the anterior, middle, and posterior cerebral arteries. The terminations of these ramify in the pia mater, and thence send many small vessels to the grey matter, and fewer, but larger ones to the white, the supply of blood to the former being much the more plentiful. That, however, which chiefly concerns the student of insanity is the vaso-motor system of nerves which controls and regulates the blood-supply. Modern research appears to render it more and

more certain that the condition of insanity, at any rate in its early and acute stage, is mainly one of increased blood-supply. On what does this depend? To this question no precise answer can as yet be given. Investigations are still being made as to the nerves which dilate and contract the vessels; but with regard to this subject, and the so-called inhibition of nervous influence, much more must be ascertained before the pathology of insanity can be definitely fixed. The lymphatics of the brain are also, according to some observers, largely concerned with the disturbance of mental function, if it should happen that by being blocked up or impeded they fail to carry off the waste products of the organ. They are contained in perivascular lymph-spaces, lying between the outer fibrous coat of the blood-vessels and a hyaline membrane or sheath of pia mater which separates them from the brain-substance.¹

Even concerning the neuroglia, controversy exists. Is it merely connective tissue, or is it nerve-structure? Authorities lean to the former view, and the increase of it in diseased brains seems to point to a growth of lower structure at the expense of higher.

Passing to the functions of the brain, the phenomena comprised under this name are of two kinds. There are the various movements excited by the stimulation of the different brain-centres, on which the experiments of Dr. Ferrier have thrown new and interesting light. But these are not the phenomena of mind. The latter can only be studied by observation of a totally different character. For mind implies sensation, feeling, consciousness, and as we have no consciousness of any feelings but our own, it is evident that here objective observation is insufficient, however unwilling physiologists may be to admit it. Yet the subjective examination of ourselves is as inadequate by itself to explain the phenomena of diseased mind, as objective observation is to make known the nature of mind in general. We must use the subjective method as our key, and by means of it open up and interpret the phenomena of mind: we may then objectively examine the mental characteristics, the growth and development, the diseases and decay of mind in all human beings, children or adults, idiots or insane, and by tracing thus the effects of injuries and disease, we arrive at a knowledge of the differences between sound and unsound mind.

By observation of the movements brought about by nerve-function, we perceive that they follow the application of a stimulus, and that many actions take place in response to stimuli which we call reflex, instinctive, or automatic, before those begin that are the product of mind in its highest sense. For mind grows slowly and gradually. The first movements of the child, reflex or instinctive, are the result of stimulation of nerve-centres, but are only slightly, if at all, attended by consciousness. This becomes appreciable later, and with it the commencement of *memory* and *ideas*, as the feelings roused by stimulation are stored away in the mind, to be reproduced as some new stimulus is

presented to them. The various brain-centres are in this manner stored with ideas, the result of experiences derived from without, and by means of the nerve-fibres they are united in groups till a most complex system is evolved. The sensations are developed into more and more complex feelings, till the highest emotions of civilized man are reached; and in a similar manner the intellectual processes grow from mere perceptions and cognitions to the highest trams of thought. Mind may be said to be made up of feelings and the relations between feelings, for the intellectual element of mind is the relational element, and it will be found that we cannot locate in two parts of the brain the emotions and the intellect, as some physiologists have proposed, for no kind of feeling, sensational or emotional, can be wholly free from the intellectual element, and on the other hand it very rarely happens that any act of cognition can be absolutely free from emotion.²

For the growth of healthy brain and mind all the conditions of physical health are necessary. If at birth there is inherited defect or accidental injury, or if at any subsequent period development is arrested or perverted, idiocy or imbecility is the result. There will be an imperfect recording of the experiences of life, an inability to learn, and a deficient power of bringing into relation one with another the various groups of nerve-centres which make up the brain, and are the seat of mind.

If, however, growth and development have proceeded normally, and normal mind is the result, what are the conditions of insanity, or disorder of mind? What are the conditions of health and unhealthy brain-function?

I. We know by experiment on nerves and nerve-centres, and by observation of the objective phenomena of motion, that a discharge of nerve-force or nervous fluid—call it what we will—is liberated when a centre is stimulated, and that this ramifies according to its quantity in various directions throughout the system. When there is health and vigour the supply will be large, and every channel both in the brain and body will be duly supplied. But in the healthiest nervous system there must in time be a cessation of this discharge, for in time the supply will be exhausted, and repair and replenishing must take place. And unless this is done, nerve-function will be impaired or cease. For the repair of the higher nerve-centres sleep is necessary, for only during sleep is the repair of the waste effected, and we commonly, nay, constantly find, that mental disturbance is preceded by loss of sleep.

In some cases want of sleep may depend on the actual time allowed for it being insufficient. Though not a very common cause of insanity, yet it sometimes is found in persons who are very hard-worked, or who, by religious exercises and services, deprive themselves of sleep. In the great majority, however, want of sleep is the result of a pathological condition of the brain, a condition which by appropriate treatment the physician seeks to remedy as the first step towards the cure of the insanity.

¹ Dr. Batty Tuke. *Morisonian Lectures. Edinb Med. Journ.*, Dec 1874

² Herbert Spencer, *Principles of Psychology*, vol. I. p. 473

Not only may there be a want of repair and replenishing of the nerve-force expended, but there may be also a defective generation and supply of it. Through anæmia or exhaustion from acute diseases or long-continued illness, the nerve-centres fail to generate from the blood the power necessary for their due operation. The discharge liberated does not ramify throughout the nervous system, calling into action every part of the brain, and penetrating to every portion of the muscular structures; thus the failing supply is manifested in the gloom of *melancholia* and the slow and torpid movements which accompany it; and when it is reduced to a still lower ebb, there may be not enough to carry on even the semblance of mind: the patient presents the appearance of utter fatuity seen in *dementia*, whether primary or secondary, and either sits motionless and lost in the condition termed *melancholia cum stupore* [Fr. *mélancolie avec stupeur*; Ger. *Schwermuth mit Stumpfsein*] or executes the purposeless and automatic movements of acute dementia [Fr. *Démence agitée*].

The defect of nerve-force may bring about insanity in more than one way. A sudden strain or shock may make an unwonted demand upon the nervous supply. Incessant thought, especially of a painful kind, may use up the reserve of force: this is not renewed, and insanity is the result, the increased molecular discharge not being duly compensated by an increased supply from the nutritive sources. Secondly, the supply may fall so far below the standard that it is not sufficient for the ordinary demands of everyday life, and so, without any mental cause, but simply from nerve-maunition, the stage of depression appears. In both of these cases, however, as in all recent insanity, the brain is in a state of hyperæmia, as evidenced by heat of head, want of sleep, and often pain and congested appearance of face. The hyperæmia impedes healthy nutrition and causes sleep to be absent, but it is erroneous to say that the brain in such patients is in a state of anæmia, even if the general bodily condition deserves that name.

II. It may be, however, that there is not so much a defect of nerve-force, as an unstable condition of the cerebral centres, which is manifested by a rapid and continuous discharge. Such a discharge in a more sudden and violent form we are familiar with in the phenomena of epilepsy. In insanity it may vary from undue hilarity and excitement up to the incessant movements and vociferation of acute delirium; and like epilepsy it may terminate in exhaustion, coma, and death. The supply of nerve force in such cases is often abundant. The patient goes without sleep for days and nights, and yet recovers. The higher brain-centres lose the power of control, owing to the violence of the discharge, and the lower and more automatic centres thus liberated are stimulated to overaction, which is manifested in noisy and violent delusions, and so on to mere delirious incoherence. And after the discharge has ceased, there may be a period of dementia and complete obliteration of mind, before the exhausted brain begins to recover. Persons who are in this condition of unstable nerve-equilibrium may be thrown off their balance by mental causes—by shock, or grief,

or losses. Their brain may also be affected by disorder of the other organs of the body *sympathetically*. In all such patients there is a predisposition, often inherited, to nervous instability and rapid discharge, and such 'causes' as puberty, pregnancy, or child-birth bring about an explosion. Here, too, there is marked cerebral hyperæmia, producing an abnormal nutrition and corresponding abnormal function.

III. Disturbance or defect of mind may be caused by incomplete development of any part concerned in mental action, or by the presence of anything within the cranium which interferes with the healthy life of the various organs. There may be tumours of different kinds, or abscess. Insanity also follows blows on the head; and deterioration of brain is frequently caused by the action of alcohol and other poisons. In all these cases we have not a functional disturbance which may suddenly arise and as suddenly pass away, but a gradually organized lesion which usually advances, producing serious and permanent results. The degeneration of the organ and tissue through age will also produce corresponding results.

SYMPTOMS.—What are the symptoms of insanity, and how far do they correspond to the pathology of brain-disturbance as set forth in the above remarks?

The first symptom usually noticed in a person becoming insane is an alteration in his *emotional* condition. Either he is more quiet and dull than usual, or, on the contrary, more restless, irritable, excitable, or hilarious. The dulness may vary from a mere disposition to sit still, and neglect his work or amusements, to actual gloom and despondency. The restlessness and excitement may also vary in degree, and be accompanied by gait or outbursts of anger and violence. The change may be more or less concealed, according as the patient can or cannot control himself. Those of his own family or people about him may notice it long before others, and this stage will vary in duration, often lasting some time before delusions or other marked symptoms are discoverable.

The *acts* of the patient will correspond to his altered feelings. His relations towards the outer world will be altered. In his torpor or gloom he will look on everything despondingly; will be unable to perform his duties, will not care for amusements, will sit at home inactive, or take up morbid fancies about his health. Conversely, he will act rashly in matters of business, embark in foolish speculations, take no heed of time or appointments, spend money recklessly, indulge in debauchery or frivolous pursuits, show causeless anger to those about him, or exhibit silly and childish hilarity when matters of grave moment are pending.

Here we have a *slight insanity*. The higher brain-centres are but slightly disturbed, and still exercise a considerable amount of control over the lower and less specialised centres. It may be difficult to say that any one act or feeling is of itself indicative of insanity, but the patient is a changed man, and the term *moral insanity* is specially applicable to this condition.

Such an insanity may remain and be permanent: more frequently, however, it either passes

off, the patient recovering, or advances in one or other of the directions already indicated. The gloom will increase; corresponding delusions will present themselves with appropriate acts and conduct; and the patient will drift into *melancholia*. Or he will become more and more hilarious, angry, excited, or suspicious, and a state will arise to which for want of a better we give the name of *mania*. Though delusions are not usually found in the stage of alteration, they are seldom absent in the second and more advanced period, and generally correspond to the feeling of the sufferer, so much so that the appearance and humour frequently enable us, without previous information, to arrive at the delusions under which he is labouring. This stage is often called *intellectual insanity*, or insanity with delusions. Patients labouring under one or other of these forms vary in the degree of insanity, from a condition in which they are able to talk coherently on many topics to one of complete incoherence or delirium. To the former the name of *partial insanity* is often applied.

Another condition is that of fatuity or childishness in various degrees. It may come on rapidly, the patient passing at once into this state, which is then called *acute* or *primary dementia*; or it may be the result of years of insanity or brain-disease, and is termed *chronic* or *secondary dementia*. In such people we find loss of memory, inability to revive the relations of feelings and ideas—not emotional disturbance, but rather an absence of all emotion.

As regards the bodily symptoms, almost every variety of insanity is ushered in by sleeplessness, sleep being deficient or altogether absent, perhaps for days, according to the acuteness of the attack. This indicates a disturbance of the brain-circulation, which is also shown by heat and pain of head, injection of the conjunctiva, and throbbing of the carotids. There may be excessive vascular action even when the insanity is the reverse of what is sometimes termed 'asthenic,' and the general condition of the patient is one of anemia rather than hyperemia.

It has been said that the mental symptoms of insanity are accidental, that they do not indicate the pathological conditions, but depend on the state of the body, and that no classification of the forms of the disorder ought to be based on them. But it is perfectly certain that the brain of a man suffering from melancholia differs altogether from that of one in acute mania. In the former there is a scanty generation of nerve-force, which is insufficient to reach the remote channels and plexuses of the brain. There is not a general incoherence and confusion of ideas, and the patient can converse rationally on many topics. His feelings are those of pain and not of pleasure, because pains in general are more intense than pleasures in general,¹ and the former are evoked into consciousness by the feeble nerve-currents, while the latter are not. In what is termed mania we may have every shade of feeling displayed, from gloomy and suspicious irascibility to great hilarity. Feelings of anger and resentment are called up without the controlling power of reflection and judgment, such

as would prevail were the whole brain at work, and the higher faculties and feelings co-operating and in relation with the lower. This, again, may be due to a want of nerve-force, or more frequently to an undue expenditure of it, as may be seen in the irritability of an over-tired child. What we may call the more automatic and less complex feelings of fear and self-love are evoked, while there is not force and pressure enough to supply the rarer and more remote qualities of comparison and reasoning which require the combination and union of the highest portions of the brain. If there is an increased and accelerated blood-flow, great hilarity and self-satisfaction may be the result, yet with perfect incoherence of ideas, owing to all the relations of the brain-plexuses being interrupted by the tumultuous or impeded circulation, and the excessive nervous discharge. And in dementia the very opposite may be witnessed. The supply of force is reduced so low that there is an absence of all ideas; memory, at any rate of recent events, is lost, and only the well-marked occurrences of earlier life are recalled.

That the mental symptoms are to be by the pathologist altogether disregarded, and that they are of no assistance in the appreciation of the pathological condition, seems a most extraordinary assertion. These symptoms do not depend on the state of the body generally, but on that of the brain, and as accurately indicate the condition of the latter as the breathing indicates that of a lung. The brain in insanity is the *pars affecta*, the insanity is the symptom, and when we see in the same individual at one time mania and at another melancholia, we may be sure that the condition of brain at the one period is not the same as at the other, though originally one cause may have lighted up the malady.

DIAGNOSIS—Accuracy of diagnosis is specially important in insanity, owing to the legal and social results which flow from it, and because the restrictions on liberty which may be necessary for proper treatment cannot be resorted to until a diagnosis has been conclusively established. The direction of the investigation will be different, according as the condition may be the result either of incomplete development, or of disablement or perversion by disease. Where *imbecility* is in question, it may often be necessary to take several opportunities of examining the patient. This condition always implies intellectual defect, though great moral depravity is often the predominant symptom. It is therefore necessary to ascertain whether any or what kind of occupation has been attempted, and what amount of incapacity has been shown, and whether the individual has proved capable of profiting by such education as he has received. Adults in ordinary circumstances ought at least to be able to read, write, and count. The decision rests on whether such capacity has been shown as is required in the ordinary conduct of life. To form a correct opinion in cases of *acquired insanity* is often a very difficult matter. The relatives of the patient often obstruct rather than aid the enquiry. They are generally divided in opinion,² and this may be partly an aid and partly an

¹ See Herbert Spencer, *Principles of Psychology*, vol. I, p. 693.

obstruction; but great care is required to avoid taking part at first with either side. Before treating the patient it is proper to make what inquiry is possible into the hereditary history of the family, the nature of the diseases or injuries from which the patient may have suffered, including any previous attacks of insanity. The ordinary habits, disposition, tastes, and occupations must be ascertained, and also the present habits, disposition, tastes, occupations, amount of sleep, and general bodily health. The mental symptoms, such as suspicions, delusions, or loss of memory, which have suggested the allegation of insanity, must also be inquired into; and special attention must be paid to any indication of the change of conduct or disposition which is so characteristic of the advent of mental disease. A reference to the articles descriptive of the forms of insanity will show the importance of all these points. In the whole investigation care must be taken to avoid accepting mere *ex parte* statements, and as much information as possible should be obtained by the inspection of letters or other documents written by the patient. Sometimes the conduct of the patient renders it difficult to obtain an interview, and care must be taken not to overstep legal limits in the attempt. If the physician has to see the patient in the presence of other persons, it is a necessary precaution to make certain that he clearly understands whom he is to examine. In obtaining the interview a certain amount of stratagem may sometimes be resorted to; but it is best that the physician should be introduced by a friend in his true character as a doctor, and on no account should any false statement be made. As a mere matter of expediency it will be found that any deviation from this produces more evil than good. If the interview takes place in the patient's home, valuable information may frequently be obtained by observation of the order or disorder which prevails. The condition of the furniture, the state of the patient's clothing, the manner of the patient towards the rest of the household and their bearing towards the patient, ought to be noted. The patient's physiognomy, the condition of the pupils and any gesticulations or convulsive or tremulous movements, must be observed. In conversation it is well to get as soon as possible to the subject of the patient's health, as it relieves many necessary questions of their offensive character. Eccentric ideas ought not to be combated more than may aid in making the patient disclose them fully; and everything tending to show the presence or absence of delusions, irrational suspicions, or loss of memory, ought to be elicited. Many other points will probably be suggested by the course of each inquiry, and the importance to be attached to them, as well as to those just mentioned, must be decided by a careful study of how far they are included or excluded by the known symptoms of any of the various forms of insanity.

Ætiology.—We now pass to the causes of insanity, which are usually spoken of as *pre-disposing* or *acting*: in many cases both combine in the causation of the disorder.

The great *pre-disposing* cause is an inherited disposition to nervous disorder—one difficult to estimate and, indeed, to discover, owing to the

care with which it is concealed, but the importance of which cannot be questioned. It has been adverted to in the second section of the pathological conditions, and will again be noticed. See *INSANITY, Varieties of*.

When we speak of such predisposing causes as *sex*, *age*, and *condition of life*, it is evident that they can only be called causes in the sense of being concurrent conditions, in some of which a man or woman is more likely to become insane than in others.

Has *sex* anything to do with insanity? Referring to statistical tables we find that in the Report of the English Commissioners in Lunacy for the year 1874 there were under treatment in asylums at the end of the year 1873, 18,872 males and 20,741 females. There were admitted during the year (not reckoning re-admissions or transfers) 6,264 males and 6,347 females, while in the same period there died 2,288 males and 1,705 females. The preponderating number of females under treatment is probably due to the fact that the mortality among them is far less than among males, and consequently they accumulate in asylums. The difference in the number of the two sexes who become insane is probably not material, but it seems that the males are the larger number, or, looking at the difference in the mortality, they would fall below the number of the females further than they do.

With regard to *age*, we find that the tendency to insanity increases with the development of brain and mind. In the first decade of life it is rare. In the second, which includes the period of puberty, it is more common, but not so much so as in the next. The period between 26 and 40 years is that in which the greatest number of cases arises, and is that of the highest development and working power. After this the number declines in each decade, as before it rose. With the age the character of the insanity varies. In youth it is displayed in violent and pyroxyamal mania, sometimes in acute dementia, and cataplectic states. There is great motor disturbance and emotional rather than intellectual aberration. Rarely are the young melancholic. In the prime of life there is active mania with delusions and intellectual insanity, and at this period we meet with the most acute forms. Later, melancholia prevails; while in old age weakness of mind, passing into imbecility and second childhood, indicates the general decay of the brain and nervous system.

As to the *condition of life* in which insanity is most frequently found, there is not much to be said. That it occurs more frequently in civilized than in barbarous countries may be assumed without recourse to figures, because in the former mind and brain are more complex, and therefore more prone to disorder. It is, however, the *failures* and *vices* of civilization that bring about the great mass of insanity. And of these the chief is *poverty*, with all its attendant physical evils of insufficient food and wretched dwellings, and moral evils of anxiety and degradation. Next to poverty, and closely bound up with it, is *drunkenness*, which among the working classes plays a fearful part in the causation of the disease. Among the *pre-disposing* causes of insanity included by the Interna-

tional Congress of alienist physicians in 1867 are, besides those already enumerated, consanguinity, great difference in the age of the parents, influence of the soil and surroundings, convulsions or emotions of the mother during gestation, epilepsy and other nervous affections, pregnancy, lactation, menstrual periods, critical age, puberty, venereal excess, or onanism. We must add to these, damage received at birth owing to difficult parturition.

The *exciting* causes of insanity are usually divided into *moral* and *physical*. Among the former we may reckon domestic trouble and anxiety, mental shock, overwork, religious excitement, political excitement, and war, and disappointment. Concerning such little need be said. They may vary in duration, some quickly bringing about insanity, others persisting for years before that result is reached. For the most part those who are affected by such causes are already predisposed by hereditary taint, by a neurotic temperament, or by being at one or other of the critical periods of life.

Among the *physical* exciting causes are some which are both exciting and predisposing—for example, intemperance and epilepsy. These may be the immediate precursors of an attack, as well as agents causing a predisposition to the disorder, by being repeated through a series of years. Other physical causes are parturition, menorrhagia, amenorrhœa, and various other ovarian and uterine ailments, diseases and injuries of the head, acute febrile diseases and chronic illness, producing exhaustion, constitutional diseases, as gout, ague, or syphilis, disease of heart and vessels, exposure to great heat or cold, lead and other poisons, anaemia, blows on the head, and organic affections of the bones of the cranium or the various parts contained therein.

CLASSIFICATION.—Almost every writer on insanity has suggested a special classification of its forms, and the majority have founded their suggestions either on the etiology or symptomatology of the disease. Of those based on symptoms none is simpler than Gruninger's—(1) states of mental depression; (2) states of mental exaltation; (3) states of mental weakness. He placed general paralysis and epilepsy apart as mere complications of insanity. His groups, therefore, correspond broadly with the old divisions of *Melancholia*, *Mania*, and *Dementia*. The etiological classification most widely known is that of Morel. He divides the forms into six—(1) *Hereditary* insanity, including congenital nervous temperament, moral and impulsive insanity, imbecility, and idiocy; (2) *Toxic* insanity, including conditions caused by insufficient or injurious food, poisons, or noxious air or water; (3) *Hysterical*, *epileptic*, and *hypocondriacal* insanity; (4) *Idiopathic* insanity, dependent on disease of the brain or its membranes; (5) *Sympathetic* insanity; and (6) *Dementia*, or the condition of terminative enfeeblement. For any systematic study of the subject, it is obvious that some symptomatological grouping, based on the characters of the mental manifestations, must be necessary. It has, however, been maintained that it is impossible, either on this or on a purely etiological basis, to found groups which have

more than an artificial relationship to one another. And there is some truth in this criticism. But, though the ties which bind the psychological groups together may be in a sense regarded as artificial, it is found in practice that the associated conditions exhibit a considerable amount of intimate natural connection.

At the International Congress of Alienists in 1867 the following classification was laid down, intended to combine the etiological and symptomatological methods—1. *Simple Insanity*, comprehending mania, melancholia, monomania, circular insanity, moral insanity, and the dementia following these forms. 2. *Epileptic Insanity*. 3. *Paralytic Insanity*. 4. *Senile Dementia*. 5. *Organic Dementia*. 6. *Idiocy*. 7. *Cretinism*.

The first class, it will be observed, comprises all the varieties which may be regarded as merely functional, the others are mostly associated with permanent structural lesions.

No classification which has been proposed can be regarded as altogether satisfactory. This is partly owing to the fact that the true nature and limits of insanity itself have been very imperfectly recognised. The essence of the condition is, of course, the manifestation of disease through some deviation from the healthy standard of mental action. It is a condition of mental unhealth analogous to bodily unhealth. But we must not allow ourselves to imagine that there is a class of morbid mental manifestations which are independent of the condition of the physical frame. The truth is that there is no pathological condition of the individual in which both mind and body are not affected, but in some diseases the mental symptoms come into prominence, in others the physical. The notion, not yet altogether exploded, that there is something in insanity altogether distinct from bodily disease, arose from the habit so long prevalent that mental action is independent of physical conditions, and from the fact that the study of insanity has been and still is too much dissociated from the study of the rest of cerebral pathology. Acting upon the broader and truer views, attempts have been made by Schneider van der Kolk, and others, to introduce a more natural system of classification. Such attempts have proceeded on the recognition of all mental symptoms as phenomena whose nature cannot be ascertained without a full consideration of the physical symptoms of disease by which they may be accompanied. Dr. Skao proposed a classification based on the belief that every mental disorder bears a relation to some bodily disease—acute or chronic—analogueous to what the delirium of fever does to the fever in whose course it is manifested. The detailed list which he offered was, however, admittedly imperfect, and it is likely that any satisfactory classification on this principle will only be arrived at after a much closer study of the mental symptoms of disease than has yet been given to them. But Skao deserves the credit of having given the most powerful impulse to the purely medical, as opposed to the metaphysical, mode of studying insanity. In furtherance of this, some progress has been made by Clouston, Batty Tuke, and others, who have published careful monographs of some of the more prominent forms. If by such means we

own group together conditions which are similar, not only in their mental but also in their physical characters, we obtain units which may ultimately contribute to the building up of a more perfect system, and which can never be altogether disregarded by classifiers in future. Most of the attempts which have been made to describe such groups must at present be regarded rather as valuable suggestions than as well-established clinical and pathological species. For the purposes of this work it has been considered best to describe in the present article, the various phases of insanity which have been regarded as of special importance, without regard to the principles which underlie their conception, and afterwards to discuss the various well-marked forms of the disease under their several heads, alphabetically arranged.

Prognosis.—The general prognosis of insanity will depend (1) on the duration of the existing disorder. Perhaps the best established fact of all is, that the chances of recovery diminish in direct proportion to the duration of the malady, and that it is consequently of the utmost importance to place a patient early under adequate and appropriate treatment. If a twelve-month elapses without appreciable improvement, the chances are decidedly unfavourable. If delusions or hallucinations remain fixed and unchanged at the end of a year, especially if there be hallucinations of hearing, the prognosis is bad. The chief exception is where there is marked melancholia. Patients will recover from this after long periods; whereas such recoveries are seldom found in insanity when depression is absent. (2) When the cause of the insanity has been of long duration, the prognosis is less favourable than when it is a passing or accidental cause. (3) Is the prognosis unfavourable in hereditary insanity? So much of the so-called simple insanity is hereditary, that we must admit that recoveries from it are not infrequent, for it is from this simple insanity that recoveries chiefly take place. Hereditary insanity is brought about by very slight exciting causes, and thus the prognosis is often favourable, and recovery takes place; but relapse is to be feared, and the prognosis in a second or third attack is not nearly so good. In this hereditary insanity, too, we frequently meet with the cases of recurring and 'circular' insanity, the progress of which is most unfavourable. Both Ray and Griesinger have remarked that the prognosis in hereditary insanity is favourable only where the individual has previously been of normal mind. When he has always been eccentric or semi-insane, and undoubted insanity at last manifests itself, the prognosis is very bad. (4) The more acute the symptoms, the greater the cerebral disturbance and incontinence, the more favourable is the prognosis, if the case is recent. Conversely, the prognosis is bad when there is little bodily disturbance, where sleep is present, the appetite normal, and the secretions unaffected, especially if persistent delusions or an entire moral change are found. (5) As all deviation from the ordinary mental state and disposition is indicative of insanity, so any return to it is a favourable sign, however trifling the circumstances may be. (6) Improvement, however slow, is a good sign

if it be progressive. So long as this goes on, recovery may take place; but many patients improve up to a certain point, and then go no farther. (7) The age of the patient must be considered. Young people recover in greater numbers than those advanced in life. The latter recover if their insanity be melancholia, but, if it be mania, with hallucinations and delusions, and obscene conduct and ideas, recovery is rare, especially if the memory is impaired, and signs of approaching dementia are present. (8) All periodicity in the disease, such as exacerbations and remissions on alternate days, is unfavourable.

Treatment.—Only a few general remarks on treatment will be offered here. Our objects should be to restore to health the disordered brain, to cause the incessant waste to cease, to promote a storing and not an expenditure of nerve-force. The brain must be nourished by healthy blood. The quantity of the litter when in defect must be increased, when its quality is in fault it must be improved, and when the blood-flow is in excess it must be checked; while all causes of disturbance reacting upon the brain from other organs of the body must be removed.

It is not to be forgotten that powerful effects are produced throughout the nervous system, both in the lower and higher centres, by what has been termed 'inhibition.' By the diversion of nervous action from one channel to another, considerable influence may be exercised.¹ Emotional excitement may be diverted into motor or intellectual channels, or, by other emotional stimuli, may be counteracted or arrested. Intellectual or ideational troubles may be diverted by emotional longings, or by countervailing intellectual pursuits. And for all this certain alignments are necessary. Painful emotional distress, with the idea of impending ruin, is perpetually fostered by the sight of the loved faces of wife and children; the patient must therefore be removed from them. Outbursts of anger are constantly directed against those most familiar, and delusions correspond. These must be abolished by his being placed among strangers. Great as is the need in many cases of medicinal treatment, it is not so universally demanded as is the removal of the sufferer to fresh surroundings. We try again and again, in apparently the most promising cases, to effect a cure at home, and we fail. The necessity for early treatment in insanity is dwelt upon by every writer; and the treatment, when insanity is once fully established, only begins after the patient is removed.

The first questions to be solved are how the removal is to be effected; and to what place the patient is to be removed. In the majority of cases, especially in the case of the urban poor, no doubt can arise—an asylum is the only place open to them, because either the friends are poor and cannot afford any other plan of treatment, or are compelled to have recourse to the public asylums of the land. For many an asylum is necessary because the patient is dangerous to himself or others, or would incessantly struggle to escape from a less guarded dwelling. But

¹ Dr Lambert Drenton, on *Inhibition*. *West Riding Reports*, iv. 172.

there are some patients who may be cured out of an asylum. Some recover from acute but transitory attacks of delirious mania very rapidly, much as do the sufferers from delirium tremens, and, if measures of safety can be taken, we may watch ~~some~~ for a few days and perchance they may recover without removal. Many persons at the very outset of insanity may by removal and judicious treatment be cured, if their friends will only open their eyes and acknowledge the threatening evil, and not wait, as they so often do, till compelled by circumstances to interfere. Such patients must not be sent abroad or out of reach, must not go alone, or without able or skilled companions. They may go from place to place, &c. to a friend's or medical man's house. Fresh scenes and fires, and the cessation of work or worry, will often effect a cure. But they must be people able to walk out in public thoroughfares, and to live in houses under ordinary precautions. Where they cannot walk in public, and cannot live in a house without its being converted into a prison, they ought to go to an asylum, where there are grounds for exercise, and where facilities for escape are not always suggesting attempts. Patients' friends constantly make a mistake: they keep the patient out of an asylum at the time asylum treatment would cure him, and send him there when all hope of cure is over, and when, as a chronic lunatic, he would be just as well off out of one.

With regard to medicinal treatment little need here be said. The drugs chiefly used in insanity are sedatives and narcotics. The writer has little faith in these, except for the purpose of obtaining sleep, and gives them only at night, except in the happily rare cases where life is in danger from want of sleep. To procure sleep no drug in his experience approaches chloral in value, and few are the cases where it is totally inefficient. He has failed to observe the poisonous effects attributed to it by some writers, and the results both in severe and slight cases have been most satisfactory. In the melancholic and non-excited cases the preparations of opium are of great service, alone, or in combination with chloral. In excitement, bromide of potassium is valuable, alone, or in combination with chloral, Indian hemp, or hyalane. Digitalis, alone or with morphia, is highly spoken of by Drs Robertson and Williams. Ergot of rye is efficacious, according to Dr Crichton Browne, in recurrent and chronic mania; and the same physician extols the virtues of calabar bean in general paralysis.

Good and abundant food is an essential in the treatment of the insane: stimulants are required in many cases, particularly the depressed and anæmic forms, but in the opposite, though often useful, they in some cases produce or increase excitement, especially in the early stage. With the food tonics should be given, and those best suited are, in the writer's experience, the mineral rather than the vegetable, and chief of all the preparations of iron.

G. F. BLANDFORD.

INSANITY, Morbid Histology of—Up to the present time no definite and distinct

lesion has been shown to accompany invariably any definite and distinct form of insanity, with the exception of general paralysis; it may, however, be considered an established fact that in every case, whether recent or chronic, a marked departure, or departures, from healthy conditions may be observed if properly sought for; but in what manner these lesions have influenced the character of the case in respect of its leading symptoms, mania, melancholia, or dementia, little as yet has been elucidated. Nevertheless, the nature of the morbid appearances is sufficient to account for perversion of functional activity, although we are unable to account for the peculiar nature of the perversion.

One great difficulty which presents itself to the mind of the cerebral pathologist is to determine whether the morbidities which are apparent on microscopic examination are of a primary or secondary nature, whether they have been efficient causes of insanity, or whether they are merely the results of mal-nutrition of the brain, and as such efficient causes of chronic lunacy. There exists an undetermined point in anatomy which, until settled, must leave the question to a certain extent open—that point is the presence or absence of cerebral lymphatics. When it is considered that the brain is an exceedingly active organ, performing many and various functions, and when it is further considered that it can obtain no vicarious aid in the performance of those functions—that it cannot, like the lungs, seek assistance from other systems—it must be at once apparent that the question of its possession of an overflow and waste products is of paramount importance. Kolmann and Arnold demonstrated to their own satisfaction the existence of a system of lymphatics in the pia mater, and His, Obersteiner, and Boll believe that the pia-matral envelope of the cerebral arteries (hyaline membrane) exercises the function of a lymphatic duct. The very existence of such a sheath or envelope has been called in question, but comparatively slight study is needed to make its demonstration certain. Although differences of opinion exist as to its relations and manner of debouchment, we believe that it terminates by funnel-shaped openings into the spaces which exist over the sulci between the pia mater and the so-called arachnoid membrane. Kolliker¹ has pointed out that the connection between the pia mater and the arachnoid over the convolutions is so complete and perfect that only at parts, namely over the sulci, a distinct space can be shown to exist. It is questionable whether the arachnoid should not be considered to be merely the outer layer of the pia mater. The bearings of this point on pathological histology will be considered under the head of cerebral congestion; it would not have been alluded to were it not that it assists somewhat in the differentiation between primary and secondary lesions of the cerebral tissues.

In prosecuting the study of the morbid histology of the brain and spinal cord, two methods of investigation should be adopted:—1. The examination of the tissues in the fresh state; 2. The examination of the parts *in situ* by means of

¹ Kolliker's *Histology*, Old Syd. Soc. vol. I. p. 466.

sections made after submission of portions of nervous tissue to hardening agents. The condition of the constituents of the recent brain can best be observed by colouring small specimens with rosaniline. The modern method of freezing, and section by means of the microtome designed by Mr. Bevan Lewis, has rendered the investigation of histological brain-changes a comparatively easy task.

The Membranes.—The dura mater is, comparatively rarely, thickened by proliferation of its elements; the vessels are found to be irregularly dilated and tortuous, with thickening of their walls.

The arachnoid and pia mater are in such close anatomical relation on the convexity of the hemispheres, that they can be best described together. Between them, supported by a delicate connective tissue, lie the blood-vessels which dip into the sulci, carrying with them an investment of pia mater, which gives prolongations to accompany them when they pierce the cerebral substance, and forms the so-called hyaline membrane. Over the sulci are the spaces usually termed sub-arachnoid, which communicate with one another by conduits accompanying the vessels. The microscopic appearances of 'milky arachnoid' have not been thoroughly described, both membranes are often thickened, presenting a laminated appearance, and the connective tissue supporting the blood-vessels is considerably increased, as well as the pia-matral prolongations accompanying the blood-vessels into the cerebral substance, which loses its hyaline character, and becomes distinctly fibrous. Extensive but thin blood-clots are occasionally found between the arachnoid and pia mater, while more rarely extravasations of blood are found between the pia mater and the cerebral substance. Deposits of hæmatoidin often surround the vessels, and their coats are frequently hypertrophied. Crystals of triple phosphate have been seen on the visceral surface of the pia mater. Lymph has been found between the pia mater and the spinal cord; the membrane was thickened, and internal to it were numerous distinct laminae of a finely fibrillated material, in some places $\frac{1}{2}$ of an inch in breadth. In one case there was long-standing epilepsy, in the other chorea, both being complicated by insanity.

The Epithelium.—The ground-glass appearance frequently seen in the ependyma of the ventricles is due to three different morbid conditions, which are, in the order of their frequency, proliferated epithelium, lymph exudations, and crystalline deposits.

When change in the epithelium is the cause of the granulations, a vertical section shows simply a proliferation of cells projecting into the ventricle, like villi.

When lymph-exudations have pushed the ependyma upwards, it presents the appearance of rough, irregular, bubble-like nodules, consisting of the layer of proliferated epithelial cells, and a greenish homogeneous stroma, which together overlie the pia mater; the same material can be frequently seen infiltrating the adjacent cerebral tissue. Deposits of phosphate of lime have been recorded as occurring beneath the ependyma of the lateral ventricles

in general paralysis, and Bergmann discovered a formation of pretty large crystals of 'double phosphate' in both plexus choroidei in a case of 'mania with mental weakness' (Griesinger, *New Syd. Soc. Trans.*, p. 429).

A proliferation of the columnar epithelium of the central canal of the medulla oblongata is not unfrequent, causing its occlusion.

The Nerve-cells.—The changes in the nerve-cells are most marked in the anterior two-thirds and superior parts of the hemispheres, as in this situation they are usually most numerous and large in size. In the depending portions of the hemispheres and the occipital lobe few, if any, changes have been noticed.

The special morbid conditions of the nerve-cells are—*A.* Atrophy, or pigmentary, granular, or fuscous degeneration. *B.* Hypertrophy. *C.* Calcification.

Pigmentary, fuscous, or granular degeneration is a very common condition in many forms of insanity, particularly senile insanity and general paralysis, and is probably to some extent a normal senile change. Dr. Major distinguishes three stages.—*1st.* The cells lose their sharply defined triangular contour, and become swollen or inflated in appearance, the process running towards the periphery of the convolution usually remains distinct, but the other processes disappear, and the cell becomes rounded off, the nucleus becomes swollen and more or less round or oval, and the nucleus is seen with great distinctness. *2nd.* A deposit of granules takes place, either external to the cell and pressing upon it, or in its interior, until it becomes more and more yellow and opaque, or both these conditions may occur together. *3rd.* The cell goes on to destruction, breaking down and shrinking, leaving the nucleus surrounded only by a mass of granules, and forming a gap in the cerebral tissue formerly occupied by the swollen cell, still later the granules entirely disappear, leaving the nucleus free. He has not observed the nucleus actually undergoing disintegration, but often no trace of it is to be found in the mass of granules left by the degenerated cell.

Hypertrophy of the large pyramidal cells of the inner layers has been observed in senile atrophy and general paralysis, as the name implies, they are large, abnormally distinct and swollen in appearance, often presenting granular masses in their interior, the processes are increased both in size and number, and the angles of the cells may be greatly prolonged or swollen and stunted.

Calcification of the cells by the deposit of phosphate of lime within their walls has been observed, according to Blandford.

The Nerve-fibres.—The chief changes in nerve-fibres, apart from their disintegration by apoplexies, softening, &c. are coarseness, irregularity and twisting of outline, and their power in the fresh state of resisting pressure under a covering glass, some becoming readily amputated. They may be affected by a pigmentary degeneration similar to that occurring in the cells; and finally they may present fusiform or oval swellings, which tint strongly with carmine, and give rise to the appearances known as amyloid bodies.

Special Morbid Conditions of the Grey Matter.—In many subjects when the pia mater is thickened and hyperæmic, a condition of the grey matter closely resembling grey degeneration in the white matter is often found; it differs from the latter by the absence of proliferated nuclei, and is strongly suggestive of lymph-infiltration, which has gradually caused atrophy and absorption of the normal structures. Circumscribed spots of yellow softening show under the microscope ragged fibres, colloid bodies, and granular corpuscles at the base of the diseased tract.

Local atrophies of the convolutions are pretty common, under the microscope a thin layer of indurated grey matter, presenting no trace of normal structure, may be found; in other cases there is simple absence of the grey matter, the white matter in both being unaffected.

The Neuroglia.—This substance undergoes inflammatory changes of a sub-acute or chronic nature, with the results of which we are familiar as more or less diffused *sclerosis*. Together with the other elements of the cerebral tissues, it undergoes atrophy in the brain-wasting of senility, and especially of senile dementia; it is also liable to special forms of degeneration, which have been called *miliary sclerosis* and *colloid degeneration*, though those terms are somewhat misleading, as the changes in question differ entirely from those generally described by these names.

General sclerosis has only been observed in one case, which is fully detailed in the *Journal of Anatomy and Physiology*, May, 1873. In a hydrocephalic epileptic idiot (whose brain weighed sixty ounces) the hemispheres varied in weight; the left being 23½ ounces, the right 30½ ounces. In the heavier or hypertrophied side, the nerve-fibres were found lying in fasciculi consisting of from four to six strands; these fasciculi were separated from one another by a clear, finely-fibrillar plasma in which nuclei existed, somewhat larger than normal.

Disseminated or partial sclerosis, or grey degeneration, is a lesion frequently met with in the brains of old-standing cases of insanity, especially in general paralysis. Its most frequent seat is the white matter of the motor tract; less frequently it is met with in the hemispheres. In the pons varoli, medulla oblongata, and spinal cord of epileptics patches of this disease are of common occurrence and in an extreme degree. When a fine section of nerve-tissue affected by this disease is examined by the naked eye, circumscribed opaque patches can be seen; in coloured sections these tracts are strongly tinted; as a rule, they are found contiguous to a vessel whose nuclei are much proliferated, and around which considerable proliferation of the nuclei of the neuroglia exists. Under the microscope, the nerve-fibres are seen to be partially or completely atrophied; the axis-cylinders and sheaths are destroyed; and the field is occupied by a finely molecular and fibrillated material, imbedded in a cloudy homogeneous plasma. In this matrix the proliferated nuclei exist, somewhat enlarged, sometimes slightly granular in appearance, but around the implicated spot they are to be seen in much

greater quantity, and not actively diseased. The atrophied nerve-fibres occasionally project raggedly into the grey matter, where they are lost. Rokitsansky believes this to be essentially a primary increase of the neuroglia. Leyden thinks it occurs secondarily to the atrophy of nerve-fibres; while Rindfleisch and others are of opinion that the first stage is marked by proliferation of the nuclei of the vessels, which is followed by an increase of the neuroglia, and the development of a morbid plasma, which is, in all probability, modified neuroglia.

Miliary sclerosis.—For the full details of this remarkable lesion the reader is referred to the *Edinburgh Medical Journal* for September, 1868, and to the *British and Foreign Medico-Chirurgical Review*, July, 1873. The following is a short account of its principal features. It is not confined to any one class of mental disease, but has been found best marked in cases accompanied by paralysis or epilepsy. It differs from all other lesions termed *sclerosis* in not being preceded, attended, or followed by proliferation of the nuclei, it is a circumscribed lesion, occurring in patches from $\frac{1}{16}$ to $\frac{1}{8}$ of an inch in length, not involving surrounding tissues, except by displacement, diffusing no morbid plasma beyond its own area, and not connected with the blood-vessels. It is essentially a disease of the nuclei of the neuroglia, and its progress is marked by three stages:—1st. A nucleus becomes enlarged, and throws out a homogeneous plasma, of a milky colour and apparently of a highly viscid consistence, forming a semi-opaque oval spot, usually unilocular, but by aggregation the spots may be bilocular, or, more rarely, multilocular. In the centre of these spots a cell-like body containing a nucleus is discernible—the original dilated nucleus of the neuroglia. 2nd. The morbid plasma becomes distinctly molecular, and permeated by fine fibrils, as it advances, the plasma round the periphery of the spot becomes more dense, and a degree of absorption of the nerve-fibres around it takes place. 3rd. The molecular matter contracts on itself, becomes more opaque, and often falls out of the section, leaving ragged holes.

Colloid degeneration may be either a primary or a secondary product, that is to say, there is reason for believing that in certain forms of insanity it is the primary pathological change, and that it is also to be met with in the brains of chronic cases as a result of long-continued perverted vascular action. It has been produced artificially in the brains of pigeons by incising them and allowing the wound to heal. This degeneration should be searched for in recent specimens. It consists of round or oval bodies, from $\frac{1}{16}$ to $\frac{1}{8}$ of an inch in diameter, bounded by a distinct wall containing a homogeneous, transparent, and colourless plasma; sometimes it is somewhat granular. The general appearance of a section may be compared to a slice of cold sage-pudding; it cannot be coloured by carmine. The condition may be regarded as a degeneration of the nuclei of the neuroglia, and is found in both grey and white matter.

The Blood-vessels.—When we examine an injected preparation of the substance of a cerebral convolution, and witness the perfection and

deficiency of its circulatory apparatus; and when we reflect on the results of the phenomena of congestion, stasis, and anæmia on the functions of other organs; we have little difficulty in comprehending the influence such conditions must have upon the highly complex elements which make up the organ of the mind. It is certain that in most cases of recent insanity, disturbance of the cerebral circulation is one, if not the essential, pathological factor; and if such disturbance is of long continuance, permanent lesions of cells, fibres, and nuclei, and, as a consequence, chronic insanity in some form, must result. The examination therefore of the cerebral vessels is of primary importance.

The following is the method of examination adopted by the writers:—After noting the degree of engorgement or anæmia in the centrum ovale, and whether on section the vessels are dragged out by the knife, vessels of moderate size should be dissected out and carefully washed with camel's-hair brushes, and then submitted to the microscope. By this mode of procedure the following changes may be discovered:—(a) Thickening or degeneration of one or other of the coats. (b) Thickening of the sheath or hyaline membrane. (c) Deposits between the adventitia and the sheath. (d) Proliferation of the nuclei.

(a) *Thickening or degeneration of the coats.*—The inner fibrous coat has been found thickened and more fibrous than in health. The muscular coat is often hypertrophied, especially the circular fibres; it is best marked in general paralysis and epilepsy. The adventitia is occasionally thickened. The whole of the coats sometimes undergo a hyaloid or vitreous change, which is probably allied to lardaceous disease.

(b) *The hyaline membrane or sheath* is often thickened and fibroid, enveloping the artery in a loosely sacculated manner.

(c) *Deposits between the adventitia and the sheath* are of two kinds; but neither is peculiar to insanity, being found in the brains of persons who have died of fever or Bright's disease with cerebral symptoms. The first is a finely molecular material of a pale yellow tint, or more often colourless, closely resembling in appearance the spores of the *Favus* fungus, and refracting light highly; it undergoes no change when treated with the ordinary oil-tests, and is found on the smallest capillaries. The particles vary in size from $\frac{1}{1000}$ to $\frac{1}{500}$ of an inch. The second form of deposit consists of irregular crystals of hæmatoidin distributed pretty equally over the vessels, except at the bifurcations, where they are aggregated.

(d) *Proliferation of the nuclei* usually accompanies proliferation of the nuclei of the neuroglia; they do not seem to increase to the same size as those of the neuroglia, but become oval or irregular in shape.

Fine sections of hardened tissue are necessary for the demonstration of the following vascular changes:—(a) Abnormalities in direction. (f) Dilatation, microscopic aneurisms, and apoplexies. (g) Perivascular spaces. (h) Syphiloma.

(e) *Abnormalities in direction* may take the form of extreme tortuosity or actual thickening; these are usually evidences of congestion, but may under certain circumstances be produced artificially.

(f) *Dilatation, microscopic aneurisms, and apoplexies.*—Ecker, Romax, and Major have found a general dilatation of the small vessels in mania and 'brain-wasting.' M.M. Bouchard and Charcot have carefully described the appearances of microscopic aneurisms; they are usually fusiform, more rarely sacculated, measuring $\frac{1}{20}$ to $\frac{1}{10}$ of an inch in length, their breadth being one-fourth of their length. These authors describe a thickening of the fibrous coats, with proliferation of the nuclei, and atrophy of the transverse muscular stria. Drs. Bastien and Hlandford have described a thrombosis of the minute vessels by masses of white corpuscles occurring in mania and delirium.

(g) *Perivascular spaces.*—In subjects who have been liable to cerebral congestion the vascular canals are often distinctly dilated, to an extent several times the calibre of the vessels, the brain substance bounding them is condensed.

(h) *Syphiloma* of the cerebral arterioles is characterised by the formation of a plastic deposit around their walls, which becomes converted into fibrous tissue, and gives to their transverse sections an enormously hypertrophied and concentric appearance, going on to almost complete occlusion of the canals.

Tumours.—Tumours have been met with in some cases of insanity, but as no growth peculiar to insanity has been described, it is unnecessary to enter into their description.

The Spinal Cord.—Microscopic examination of the spinal cord has not revealed any lesion peculiar to the various forms of insanity, excepting general paralysis. Drs. Westphal, Meredith Clymer, Boyd, and others are of opinion that in this disease well-marked departures from health are to be found. The first-named pathologist describes an atrophied condition of the cells of the posterior columns, with increase of their connective tissue, commencing externally and extending inwards; he also believes in a chronic myelitis affecting the posterior columns and the posterior sections of the lateral columns. As far as the writers have been able to observe, this is by no means an invariable accompaniment of this disease, although in one case it was undoubtedly present. The cells of the cord were in most instances undergoing fuscous granular degeneration, like those of the hemispheres.

The Sympathetic System.—The sympathetic ganglia undergo a pigmentary degeneration in various forms of cerebral disease.

J. BATTY TUKER.
ROBERT SAUNDY.

INSANITY, Varieties of.—In this article various forms of insanity will be described under separate heads. DEMENTIA, GENERAL PARALYSIS OF THE INSANE, MANIA, and MELANCHOLIA will be found in other parts of the work.

1. **Alcoholic Insanity.**—The conditions included under this head must not be confounded with what is called dipsomania. In the latter affection the indulgence in alcohol is a symptom, and not necessarily a cause; while here the insanity is always a direct result of some form of alcoholic poisoning. It is met with in three forms, namely, *acute alcoholic insanity*, *chronic alcoholic insanity*, and *delirium tremens*.

Acute alcoholic insanity seldom occurs except when there is a strong hereditary tendency to mental disturbance, or when the cerebral energies have been notably impaired by excesses or overwork. Where all these predisposing causes exist, it may not require a large dose of alcohol to bring on an attack. The most frequent form of the affection is violent maniacal delirium, known as *manis a potu*, with a tendency to homicidal acts. In some cases the mental disorder takes the melancholic form, and it becomes necessary to guard specially against the strong suicidal tendency which generally characterises it. Unless the brain has been weakened by repeated attacks, both forms are curable and generally of short duration. The treatment is the nourishing, non-stimulating regimen detailed in the articles on Mania and Melancholia.

Chronic alcoholic insanity is one of the results of chronic alcoholism, and there is no condition which better illustrates the 'solidarity of the psychical and somatic functions of the nervous system' and the interdependence of their morbid manifestations. The physical symptoms are fully described in the article on ALCOHOLISM; the mental symptoms are generally present from the beginning, though not always prominent enough to attract special attention. The sleeplessness, so characteristic of commencing mental disorder, is an early symptom; then restlessness and depression, with suicidal tendency, sometimes passing rapidly into complete dementia, but generally passing gradually through a course of moral and mental degradation, which progresses step by step with the symptoms of failure of physical nervous power. The affection presents many points of resemblance to general paralysis of the insane, and is in some cases only to be distinguished from it by obtaining evidence of alcoholic poisoning, and by the persistence of the mental depression, which is seldom more than a transitory symptom in the general paralytic.

Delirium tremens is described fully under the heading of ALCOHOLISM, but it is proper to note here that after the acute symptoms of that disease have passed away, there is sometimes left behind a state of subacute insanity of a characteristic nature. At first suicidal symptoms are apt to appear. Suspensions of poisoning, fear of impending evil, and hallucinations of hearing are also frequent. The treatment required is constant companionship of a trustworthy attendant, exercise, fresh air, and change of scene, with attention to every ordinary means of restoring the functions to a healthy state. Under proper treatment the prognosis is favourable.

JOHN SIBBALD.

2. Amenorrhœal Insanity.—Mental derangement is often accompanied in females by suppression of the menses. But in many such cases the insanity cannot be called amenorrhœal, as the cerebral and uterine disorders may only be associated as both symptomatic of some debilitating cause affecting the whole system. Then the mental condition is usually the depression produced by anæmia. But there is a mental derangement directly resulting from sudden suppression of the catamenia, to which this distinctive name is not inaptly applied. Here the insanity

takes the maniacal form. It is sometimes ushered in with urgent febrile symptoms, in which case the mania assumes the acutely delirious character. Where general febrile disturbance is not prominent, the mental condition is more simply maniacal, and sometimes does not get beyond mere irritability with delusions. The pathological condition must in either case be regarded as mainly a hyperæmia of the brain.

TREATMENT.—This must be directed towards the restoration of the arrested discharge. If the patient be seen at the commencement of the attack, the hip-bath and a gentle purgative may recall it. If the menstrual period has passed, the attention of the practitioner must be devoted to the relief of the more urgent symptoms. If the symptoms of cerebral congestion are distinct, leeches will probably be found useful. Regular action of the bowels should be secured, but active purgation should be avoided. The food ought to be easy of digestion, and care should be taken not to let it be deficient in quantity. If the mental excitement is great and long-continued, it will necessarily produce considerable exhaustion, and the condition of the patient after recovery from the mental excitement will depend very much on the extent to which the strength has been supported during the continuance of this strain. The re-appearance of the catamenia generally implies recovery of mental health; but cases occur where prolonged amenorrhœa leads to a chronic maniacal condition, ultimately passing into hopeless dementia.

JOHN SIBBALD.

3. Choreic Insanity.—There appears to be an intimate connection between the pathological basis of chorea and a certain disturbance of the mental functions. The physical and the mental symptoms however do not necessarily correspond in intensity. Sometimes where the convulsive symptoms are very severe, the mental condition is merely one of dulness, apathy, or irritability. In children it shows itself generally in a maniacal restlessness, accompanied by delirium of a peculiarly automatic character. It is frequently associated at all periods of life with the rheumatic condition, and hence it has by some authors been called rheumatic insanity. It generally commences with sleeplessness and delirious excitement of a remittent character, which is sometimes accompanied by violent convulsive effort. As the excitement passes off, delusions of suspicion are apt to arise, and these are strangely associated with an apathetic mental condition. In the acute form the prognosis is favourable, recovery generally taking place in from four to eight weeks. The chronic form is apt to pass into dementia.

JOHN SIBBALD.

4. Epileptic Insanity. See EPILEPTIC INSANITY.

5. Feigned Insanity.—Insanity may be feigned in order to escape the obligation of duty, or the consequences of crime. If manifested at a time when its recognition might be a benefit to the individual, it becomes necessary to test its reality. It must not be rashly inferred in any case that insanity is feigned; for it sometimes results from the excitement consequent on a sense of guilt or

the shock of a false accusation; or it may arise accidentally but independently of such conditions. The best preparation for making a satisfactory examination in such a case is a familiar acquaintance with the appearance and conduct of persons undoubtedly insane. A person feigning insanity must, to be successful, simulate some known form of the disease; and as each form presents a more or less definite group of symptoms, an impostor is apt to reveal the truth by omissions or by additions inconsistent with the part that he attempts to play; but the mistake generally made by the impostor is to over-act the part. The inquiry may, of course, assume various aspects. A person may pretend to have been insane at the time a certain act was committed. Here it is to be remembered that the insanity, if real, would not probably have been confined to the time of the commission of the crime, and some evidence of premonitory symptoms previous to the act would probably be found. In such cases it is proper to regard want of motive as so far an indication of insanity; but when the supposition of a sudden mental perturbation is put forward, some reason would have to be shown for its occurrence; and some history of the occurrence of cerebral injury, or of previous attacks of insanity, epilepsy, or other cerebral affection ought to be forthcoming. A person feigning to be insane at the time he is examined must endeavour to present symptoms of either mania, melancholia, monomania, dementia, or imbecility. When the symptoms arise suddenly, simulation of the maniacal condition is generally attempted. The exertion which this entails will, however, generally compel an impostor to exhibit symptoms of fatigue, and even to sleep, when the true maniac would exhibit persistent excitement. The raving also when feigned may be recognised as hesitating and premeditated. Forgetfulness, which is generally assumed by the impostor, is an unfrequent symptom of mania, except when it occurs in the course of general paralysis, and this is a disease whose other symptoms could scarcely be simulated. If melancholia or monomania be feigned, the chief facts to be borne in mind are that such conditions, when real, are very unlikely to arise suddenly where there are no symptoms of bodily disease to account for them; and that they are usually characterised by a tendency to conceal peculiarities, or at least not to push them ostentatiously forward. Dementia never occurs suddenly without evident cause. A class of cases occur in which insanity is only partially feigned. Young criminals frequently try to exaggerate the signs of the intellectual weakness which is so generally mingled with their moral depravity, in hopes of obtaining a relaxation of discipline, or a transference from a prison to an asylum. Such cases are often full of difficulty. The principle which ought to regulate our action is to avoid the continuance of punishment when disease or deficiency renders it useless. Before deciding upon the reality of any doubtful case of insanity, all the physical conditions of the individual, such as the amount of sleep, the state of the pulse, skin, tongue, and digestive system generally, the conduct and the state of health immediately preceding the signs of insanity, should be ascertained. The effect of remarks made within hearing of the

suspected person should be observed; one who proclaims his own insanity should be distrusted. And the medical history of the family and of the individual should be inquired into, with a view to disclose anything which might have caused insanity or predisposed to it.

JOHN SIBBALD.

6. *Gastro-Enteric Insanity.*—The emotional condition is well known to be to an appreciable extent dependent on the state of the *prime vie*; and where the nervous system is predisposed to derangement, certain affections of the stomach and bowels seem sufficient to produce insanity, and to stamp it with a special melancholic character. In addition to the mere depression caused by anæmia, there is associated with such affections a peculiar anguish of mind, and tendency to self-accusation, which is often of the most distressing nature. Refusal of food is frequently a prominent symptom. The intellectual perversion is often slight, and seldom so prominent as in other acute insanities. Relief of the bodily symptoms is generally accompanied by a return to sanity. The affections which have been most frequently observed to produce this form of melancholia, are irritation and catarrh of the mucous membrane, constipation, stricture or other causes of distension of the viscera, and pressure upon the stomach or intestines by tumours in the epigastric region. Schroeder van der Kolk described the mental symptoms as being always due to affections of the colon; but disease of other portions of the canal—as the rectum and anus—seems also to produce them.

JOHN SIBBALD.

7. *Hereditary Insanity.*—SYNON. *Fr. Folie héréditaire*; *Ger. Erbliche Geisteskrankheit*.—This implies insanity symptomatic of hereditary weakness of the nervous system, generally coming on without the intervention of appreciable exciting cause.

The nervous system seems to be peculiarly liable to be involved in the effects of hereditary degeneracy, and this is frequently evinced by the occurrence of mental symptoms. The ages at which these are developed, and the character which they exhibit, depend both on the nature and on the strength of the hereditary disposition. The forms of insanity, however, which seem to be most directly the result of hereditary influence, generally make their appearance at those periods of life when either rapid structural development takes place, special functional activity is first exhibited or is ultimately arrested, or upon the advent of senile decay. The ordinary exciting causes of insanity may also affect persons at these periods, and in such cases the resulting disorder will be stamped more or less distinctly with the impress of its origin. But where these forces do not come powerfully into play, it is found that hereditary insanity exhibits a special character according to the period at which it is developed. We have thus an *insanity of pubescence*, a *dementia* *insanitas*, and a *senile insanity*. Idiocy and imbecility (which will be found discussed under their respective heads) are also frequent results of hereditary weakness, showing itself during fetal life, or during the period of dentition; and the

mental derangements which often affect women at parturition, and during the processes which precede or follow it, seem to occupy a position in the pathological scale intermediate between the *periodicity* and the accidental form of insanity.

Insanity of pubescence is a condition not unfrequently met with, and one which it is very important to recognise early in its true character. Much unintentional injury is frequently done by the patient being at first regarded as a delinquent and treated accordingly, instead of reserving the careful management suitable to the disease. The affection is characterised by great disorder of the emotional and moral nature, which is evinced by restless though seldom violent excitement, eroticism, acts of purposeless mischief, and exhibitions of inordinate vanity. Any marked change of disposition during the passage from youth to adult life ought to be regarded as probably pathological in its nature, and must be carefully watched. Persistent sleeplessness at such a time must also be regarded as significant of danger to the mental functions. The physical condition is indicated by capricious appetite, and symptoms of anemia. The treatment required is rest to the mind, both in its intellectual and emotional energies, with cultivation of everything likely to develop physical vigour. If the hereditary tendency is not exceptionally strong, or aggravated by accidental causes, the prognosis is not unfavourable.

Choleraic insanity occurs in males between the ages of fifty and sixty, and in females between forty and fifty. Its general character is a form of melancholia, gradual in its development, manifesting itself in loss of sleep, fear of undefined evil, religious despondency, hallucinations of the senses, refusal of food, and frequently in a suicidal tendency. Excitement and exaltation occur rarely, and are generally of short duration. The mental disorder is frequently accompanied by very marked emaciation, and the tendency is always to anemia. The treatment required at the commencement is cessation of mental labour and change of scene. During the whole progress of the disease the diet should be full and nourishing, and the digestive functions often require to be stimulated to healthy action. In the majority of cases the prognosis is unfavourable, and where recovery does not take place within one or at most two years the course is generally towards dementia.

Senile insanity is essentially a form of dementia, which comes on gradually in persons who have passed through the earlier periods of life without disturbance of their mental health, but who break down in old age. Its principal features are loss of memory, slight excitements, whimsical likings and dislikings, querulousness, and a gradual decadence into fatuity. It is subject to occasional remissions, which are sometimes very short, as when caused by the stimulus of acute febrile conditions. But they are sometimes so prolonged as to amount practically to recovery. Not infrequently the breakdown of the nervous system pursues a rapid course, and in such cases there is often a marked similarity in the symptoms to those of general paralysis. Both mental and physical conditions in the advanced stages of each are sometimes

practically indistinguishable. The diagnosis will depend on whether the characteristic first stage of general paralysis has been observed at the commencement, or only a gradual loss of physical and mental power. Paralytics, moreover, are seldom of advanced age.

JOHN SINIBALD.

8. *Impulsive Insanity.*—Violent acts are committed under an insane impulse by numerous patients whose insanity is plain and acknowledged. They may be done under the influence of delusions or hallucinations, but the term *impulsive insanity* is commonly applied to a disorder manifested, not by delusions and similar symptoms, but by acts of violence to which a patient is driven by blind, uncontrollable, and morbid impulse, whereby the will and the reason are overpowered for a longer or shorter time. These are for the most part acts of *suicide* or *homicide*; and in connection with the latter, great controversy has arisen as to the responsibility of persons committing them. Here, as in moral insanity, there are no delusions; frequently no change will have been detected in the individual prior to the act, nor will there be observers of it. And it is a fact that the impulse may be satisfied and exploded in the act, and having thus found a vent may be felt no longer, at any rate for a time. It may be as sudden as an epileptic fit, and may, like the latter, bring relief to the brain. Indeed, there is a strong connection as well as analogy between the two disorders, and, as Dr. Maudsley says, instead of a convulsive movement there is a convulsive idea.

In estimating such acts as these we must not only consider the act itself and the manner of its performance, but must also closely inquire into the past history of the perpetrator and his progenitors. For all this we may or may not have opportunity. If the act is one of attempted suicide, and the individual is kept under observation, we may have no difficulty in diagnosing insanity. If it is one of homicide, and the criminal is in prison for, perhaps, only a week or two, opportunity of ascertaining the history of his family may fail, nor will he himself be under skilled observation. Moreover the period just after the commission of an impulsive homicide will very probably be the one in which fewest symptoms of insanity will be noticeable. The period immediately preceding it will be that which most closely demands a scrutiny, but we may be able to get no information if the accused has been moving from place to place, has been among strangers, or has had those about him who were obtuse and unobservant. Many an act of suicide and homicide would be prevented if the friends would not shut their eyes with such pertinacity to the strange and altered looks and conduct of the patient. But in this impulsive form, although there may not have been enough to warn those about a man to restrain him, there may have been symptoms which are sufficient subsequently to indicate to a physician the presence of mental disorder. There may have been attacks of *grand mal* or *petit mal*: there may have been former attacks of insanity, periods of, it may be, slight depression, which, though they may have attracted little notice at the time,

may indicate an insane delirium. The sufferer may have been sleeping badly or have taken less nourishment than usual.

The medical witness will, in the case of homicide, carefully examine and pay special attention to the following points:—

(a) The nature and character of the act must be noted. The presence or absence of motive may often assist us. When the victim is near of kin and dearly loved, suspicion of insanity will at once arise. When, on the other hand, it is a perfect stranger, never before seen, where there has been no previous meeting or quarrel, the same suspicion will arise. The method of the act may guide us somewhat, but not so much. There may be premeditation, though generally there is not.

(b) The demeanour of the prisoner after the act may assist us. Were there, or were there not, attempts to conceal it, or to escape detection and arrest? What was said in explanation? It sometimes happens that there is complete unconsciousness or forgetfulness of what has occurred, and we may then strongly suspect the presence of epilepsy.

(c) We must closely inquire into the family history, and shall often find that in cases of impulsive homicide, the family of the accused is saturated with insanity. And where this is so, we may also find that from youth the accused has been deficient and weak in intellect, or odd and eccentric. The weak-minded, in fact, may be grouped in a special class of homicides. As there is a weak-minded moral insanity, so there is a weak-minded impulsive homicidal insanity the sufferers from which have not unfrequently been hanged, their insanity not having been sufficiently marked to absolve them from legal responsibility. Fits in childhood may contribute to this state. And throughout, at the age of puberty, or in adult life, there may be slight but sure indications of the insane blood that has been inherited, which are displayed in an impulse to homicide or suicide, even as in others the tendency is shown in ordinary attacks of insanity.

(d) We must look very closely for symptoms or a history of epilepsy. Such indications as nocturnal micturition or a bitten tongue may guide us to the truth. While in acknowledged epileptics it may happen that the homicidal attack takes the place of the ordinary convulsion, and without the occurrence of the latter there may be a period of unconsciousness and unconscious action lasting, perhaps, for days. See **EPILEPTIC INSANITY**.

The occurrence of one homicidal attack of a strange or anomalous character may make us fear its recurrence, and when we have to examine a criminal who has committed one act of this kind, it is important to inquire whether he has ever at any former time done any sudden act of violence of a similar description. For this reason such patients should not be released from an asylum, except under great and special precautions.

G. F. BLANDFORD.

8. Legal Insanity.—Lawyers regard insanity from a different point of view from medical men. A medical man applies his mind to its study so

as to ascertain how far he may infer from the evidences of mental action the existence of morbid conditions which he may hope to alleviate or remove. It is therefore his duty to be acquainted with such symptoms as give the earliest indication of the approach or development of these morbid processes. For it is during their initiatory stages that he may most successfully intervene with the resources of his art, to check their progress or to ward them off. He therefore identifies with the existence of disease, every deviation from the healthy mental standard which indicates the necessity for medical treatment or advice. A lawyer, on the other hand, takes note of insanity only in so far as it affects the safety of person or the preservation of property. The question which he seeks to determine is whether a person is justly responsible for certain acts which he has committed, or is competent to perform certain acts which he may be called on to perform. It is evident, therefore, that the legal view of insanity must naturally be much more limited than the medical. 'A lawyer, when speaking of insanity,' says Mr. Justice Stephen, 'means conduct of a certain character; a physician means a certain disease one of the effects of which is to produce such conduct;' and though this has been adversely criticised it seems to show correctly the directions in which the two views diverge. They might perhaps be as fairly indicated in other words if we say that the lawyer has to deal with the nature or quality of certain acts, while the physician has to deal with the condition of certain persons. No satisfactory general definition of legal insanity has been given. In the earlier ages of our legal system none but the most outrageous cases of insanity were recognised. Bracton in the thirteenth century defined a madman as 'one who does not understand what he is doing, and, wanting mind and reason, differs little from brutes.' Sir Edward Coke, though he recognises different classes, according as the insanity is congenital, permanent, or temporary, only admits that a person is insane when he is *non compos mentis*, or has wholly lost his memory and understanding. Sir Matthew Hale, in the seventeenth century, was the first to recognise the existence of less extreme forms of insanity. 'Some persons,' he said, 'that have a competent use of reason in respect of some subjects, are yet under a particular dementia in respect of some particular discourses, subjects, or applications; or else it is partial in respect of degrees, and does not excuse persons who commit capital acts in this state.' He also said that it is 'very difficult to define the invisible line that divides perfect and partial insanity,' and 'that most persons that are felons, of themselves or others, are under a degree of partial insanity when they commit these offences.' The recognition of these gradations, reaching even to the mutual overlapping of crime and insanity, indicates as much breadth of view as could be expected at a time when the very judge who recognises them passed sentence of death on persons convicted of witchcraft. We cannot doubt, indeed, that at that period the ignorance of the nature of insanity was such that many lunatics were executed for this offence. The recognition of the necessity of taking legal account of minor degrees of insanity

than 'furious madness' or idiocy may be said to commence at the beginning of the present century. The mode in which unsoundness of mind comes into relation with law at present, may be looked at most conveniently from three points of view:—1. Where a person suffers from such unsoundness of mind that it is necessary for his welfare, or the safety of the public, that his liberty should be restricted by his being placed in an asylum or subjected to similar restraint. 2. Where a person suffers from such unsoundness of mind that he is incapable of managing himself or his affairs. 3. Where irresponsibility for crime, on account of insanity, is pleaded in a court of law. It will be found more convenient to consider these three relations of insanity and jurisprudence separately. The reader is consequently referred to the articles specially devoted to them, which will be found under the heads of LUNACY, LAW OF; CIVIL INCAPACITY; and CRIMINAL IRRESPONSIBILITY.

JOHN SIBBALD.

10. Moral Insanity.—SNOW: *Fr. Manie sans délire; Folie raisonnée; Monomanie affective; Ger. Gemüthsirrthum.*

Under the names of *moral insanity, emotional insanity, impulsive insanity, affective insanity*, has been described the disorder of certain patients, which is manifested by insane actions and conduct rather than by insane ideas, delusions, or hallucinations. Such persons are sometimes said to be of whole and perfect intellect, though unsound in the moral and emotional part of their brain. They come under the notice of medical men, not so much for purposes of treatment as for diagnosis. Their conduct being chiefly displayed in foolish or violent acts, they require to be restrained, and the question arises: Is this conduct badness or madness? are they responsible for it or not?

Dr. Maudslay gives *moral insanity* and *impulsive insanity* as two subdivisions of *emotional or affective insanity*; and, as the symptoms are certainly different, we cannot do better than consider them under separate heads. But certain observations are applicable to both. In neither will there be found delusions, and as delusions are, in the opinion of some, especially lawyers, necessary to the establishment of legal insanity and irresponsibility, those patients are not legally insane. Another remark is that this moral or impulsive insanity does not constitute a definite and well-marked disease, like acute delirium or general paralysis. Every patient may at one time or other be 'morally insane,' that is, may not have reached the stage of delusions, or may have recovered from it, and every patient may commit 'impulsive' acts of violence, whether his insanity is displayed in other ways or not.

By *moral insanity* is to be understood a disorder of mind shown by an entire change of character and habits, by extraordinary acts and conduct, extravagance or parsimony, false assertions and false views concerning those nearest and dearest, but without absolute delusion. Such a change may be noticed after any of the ordinary causes of insanity. It may follow epileptic or apoplectic seizures, or may be seen after a period of drinking. Its approach is gradual, as

a rule, rather than sudden, and the extraordinary character of the acts may not at first be so marked as subsequently. Friends wonder that a man should say this or that, or should do things so foreign to his nature and habits, but some time may elapse before they can convince themselves that such conduct is the result of disease, and the acts may be such that many will look upon them even to the last as signs merely of depravity. Such insanity of course varies in degree. When it is well marked, and the conduct is outrageous, there will be no difficulty in the diagnosis. But it may be less marked; it may consist of false and malevolent assertions concerning people, even the nearest, of little plots and traps to annoy others, in which great ingenuity and cunning may be displayed. And there will be the greatest plausibility in the story by which all such acts and all other acts will be explained away and excused. It would seem sometimes as if a universal badness had taken possession of the individual, yet a badness so inexplicable that it can only be looked upon as madness. Where we can ascertain that this condition of things is something which has come over the patient, being formerly absent, and that he is altogether changed, we may suspect insanity. But much examination and opportunity for examination may be needful before we can sign a certificate, for such people are often very acute, and quite on the alert. They have no scruples about falsehood, and will deny or justify everything with which they are taxed; and where the insanity is manifested in conduct, the medical man may never be a witness of it, and is obliged to receive on hearsay that which the patient strenuously denies. Careful inquiry, however, will probably reveal the origin and cause of the change; there may have been a period, though short, of acute insanity—as acute mania or melancholia—which passed away and left this as a permanent condition; or it may be the precursor of a more advanced stage of the disorder, one marked by the ordinary symptoms, as delusions and hallucinations. If the change has been rapid and progressive, if the sufferer has become more and more outrageous and eccentric, it is likely that in a short time unmistakable insanity will be displayed; but some cases progress slowly, and steps for restraint have to be taken before anything like delusion is to be found. It may be necessary to prevent a man from squandering all his property—a common symptom in this variety—or from wandering from home and absenting himself no one knows where, or keeping low company. And when a man previously quite sober suddenly takes to drinking, the question may arise whether this is not the effect of insanity. Great difficulty may be found in proving the latter, but unquestionably it is often the case. Here, however, if the habit is indulged in, the patient will most likely get rapidly worse, and then restraint will be more easily enforced.

Moral insanity may be the precursor of general paralysis; it may also be the sequel and result of a more severe insanity; it may be the outcome of apoplexy, or of a blow or other damage to the brain. It may be one of the alternating states of the so-called *Folie circulaire*. Here a period

of depression alternates with one of excitement, gaiety, self-glorification, or insatiability, and the latter may be one closely resembling that usually called moral insanity, and evidenced by exaggerated conduct and absurd acts. It may follow a simple attack of epilepsy, or may be the precursor of such attacks, being a part of that epileptic condition known as masked epilepsy. See *EPILEPTIC INSANITY*.

The one constant and marked feature of this insanity is the absence of delusion; but we are not on this account to argue that the intellect is sound. There is often great acuteness and cunning displayed by such patients, yet along with the cunning there may be the most silly and foolish conduct. Often there is great acuteness shown by those who have delusions, but because of the latter we say their intellect is disordered. Yet it is proof of disorder of the intellect if a patient spends his capital as though it were income, defrauds and justifies the most outrageous acts, and cannot be made to see that they are outrageous. Close examination will probably reveal the fact that there is very considerable intellectual lesion in these cases. There is a want of the power of attention and concentration of ideas on a subject. A patient commences a story of his grievances, and in two minutes is far away from his theme, and is boasting of his virtues or conduct, and no amount of bringing back will enable him to give a definite and succinct account of what he has to complain of. Such rambling is a marked symptom of this insanity, and a strong indication of a weakened intellect.

There is one more form of moral insanity which is, perhaps, the hardest of all to diagnose and estimate. It is the congenital moral defect occasionally met with in persons who have been from birth odd and peculiar, and incapable of acting and behaving like other people. They can hardly be called idiots or imbeciles, for they may exhibit a considerable amount of intellect and even genius in certain special directions. We shall generally find that they are the offspring of parents strongly tainted with insanity, epilepsy, or alcoholism, and many in childhood are the subject of fits, chorea, or other neuroses. They are incapable of being instructed like other boys and girls, are often frightfully cruel towards animals or their brothers and sisters, and seem utterly incapable of telling the truth or understanding why they should do so. Here there is no change; we cannot compare the individual's condition with a former one, but we can only estimate him by the average of mankind. These are the persons who commit crimes and become the chronic inmates of prisons, and it is most difficult both for medical and other prison-officials to say how far they are responsible, and how far not. Careful and special education is needful for them, and this they may obtain if they are born of well-to-do parents, but a vast number are to be found amongst the ranks of the lower classes; the offspring of intemperance and poverty, they swell the numbers of the criminal classes in no inconsiderable degree.

G. F. BLANDFORD.

insanity associated with pellagra, and not met with in Britain. It is characterised by mental symptoms usually indicative of anæmia—great depression, frequently with tendency to suicide, passing on to chronic dementia. It is more frequently met with in Italy.

12. Phthisical Insanity.—It has been generally observed that there is a special mental character associated with pulmonary tuberculosis. This consists frequently in a peculiar cheerful hopefulness, which has received the name of *spes phthisica*, and which seems strangely out of harmony with the unmistakable signs of an inevitable doom by which it is accompanied. But there is also a state of mental depression which has been observed in intimate association with the disease. The peculiar hopefulness is most frequently met with in the acute and active forms of phthisis, and it is often so irrational and persistent as to amount to an insane delusion, growing as it does in strength while the evidences of its baselessness accumulate. In the last stages of the malady the religious and general emotional exaltation is often extreme, and actual delirium is not infrequent. An opposite mental condition is met with in chronic phthisis, more especially in that form of it which has been called latent. All through the course of the disease there is a prevailing depression and distrustfulness, though the physical symptoms are neither so distressing nor so obvious as in the acuter forms. The mental symptoms sometimes precede the physical. Languor and depression, mingled with waywardness, are characteristic of the initial stage. This is usually accompanied by general functional debility, which is often attributed to mere disturbance of digestion and nutrition. The skin is habitually pale, and the circulation feeble. In many cases the physical signs of pulmonary disease when present are apt to be overlooked, and occasionally they escape observation for years. Where the mind is much affected the ordinary symptomatic cough, expectoration, and dyspnoea are often absent, and this is the case sometimes where physical exploration reveals the existence of extensive bronchæ and other characteristics of advanced disease. The mental condition as the further stages are reached becomes less one of depression and more one of distinct enfeeblement. Occasional fits of considerable irritability and excitement occur. Dr. Clouston, who first drew special attention to this condition, says of the patients that 'there is a want of fixity in their mental condition. There is a disinclination to enter into any kind of amusement or continuous work; and if this is overcome there is no interest manifested in the employment. It might be called a mixture of subacute mania and dementia, being sometimes the one and sometimes the other. As the case advances, the symptoms of dementia come to predominate; but it is seldom of that kind in which the mental faculties are entirely obscured, with no gleam of intelligence or any tendency to excitement. If there is any tendency to periodicity in the symptoms at all, the remissions are not so regular, nor so complete, nor so long as in ordinary periodical insanity. If there is depression it is accompanied with irritability and the want of

11. *Pellagrous Insanity.*—This is a form of

any fixed depressing idea or delusion. If there is any single tendency that characterises these cases, it is to be suspicious. Where any chronic form of insanity is associated with phthisis the chance of complete restoration to sanity is very small. In the affection distinguished by emotional exaltation no special treatment is called for. The only indication of treatment in the other type of disease is the necessity of keeping up a full supply of nourishment to the brain; and this sometimes requires that forcible feeding should be resorted to. Where the mental condition is much disturbed, a trustworthy attendant ought to be employed, and the general treatment should always be tonic and stimulating. Removal to an asylum ought in most cases to be avoided.

JOHN SIBBALD.

13. Puerperal Insanity—*SYNON.* *Insania gravidarum, Insania puerperarum, Insania lactantium, Fr. Folie puerperale; Ger. Puerperal-manie.*

DEFINITION.—Insanity developed during pregnancy, parturition, or lactation.

It has been the custom of authors, till a recent period, to include under this heading the forms of insanity which occur in females during the periods of utero-gestation, the puerperal state, and lactation. It is now frequent to find the term 'puerperal' restricted to the derangements which come on at the time of delivery, or within a short period thereafter. Whatever notice we adopt, it is impossible to consider the insanity occurring at these different periods quite independently. The condition of the woman during the whole process, from the time of conception till the child is weaned, represents one of those physiological crises during which congenital or acquired weakness of constitution tends to show itself.

The *insanity of pregnancy* generally takes the melancholic form, and seems to be due in some cases chiefly to a gradually developed anemia, and in others to disturbance of the abdominal viscera, both of which conditions are frequently associated with mental depression. The delusions which characterise the disorder are generally exaggerations of the anxieties and whims so frequent in pregnancy. In the severer forms the suicidal impulse is frequently developed. The prognosis is generally favourable; but recovery seldom occurs till the termination of the gestation. It may sometimes be expedient to resort to the induction of premature labour. In all cases a torpid condition of the digestive functions should be carefully corrected.

Puerperal insanity in its more restricted meaning is frequently understood to include all derangements occurring at parturition, or within six or eight weeks after it. But it is better to limit the term to what occurs during the first three weeks, as the form of disorder which commences after that period is generally different in character.

ETIOLOGY.—Prominent among the causes of puerperal mania are all states of debility, either induced before parturition by want, intemperance, disorders of nutrition, or rapid succession of pregnancies, especially if lactations and pregnancies are carried on simultaneously; or it may be the

result of weakness induced during parturition by hæmorrhage or exhaustion. It is liable to occur in primiparae, when the subjects are either exceptionally young or exceptionally advanced in life. Irritation arising in the pelvic organs, intestines, or mammae also tends to produce it. Any inordinate mental excitement or depression is apt to bring it on. Where any of these causes are superimposed on hereditary tendency, the danger is of course greatly augmented.

SYMPTOMS.—Attacks of maniacal excitement sometimes occur during actual parturition. They are usually of very short duration, and seem to be directly dependent on the intense suffering which may accompany the pains. The most frequent period of their occurrence is when the head of the child is passing either the *os internum* or *externum*. The more serious phase of the disorder is in its acute stage a variety of acute maniacal delirium. It usually commences within a week or ten days after delivery. Generally it is preceded by sleeplessness, and the patient manifests more or less apprehension of coming evil. Sometimes, however, she awakes delirious from what had been regarded as a healthy slumber. When the attack has commenced, sleep is always either very imperfectly obtained, or is altogether absent. The pulse is quick, the skin often, but not always, dry and hot; and the head throbbing. The eyes are bright, and the face generally pale, with occasional flushing. The expression is generally indicative of alarm or suspicion on the part of the patient. The tongue is dry and furred, and the secretions of milk and lochia are either suppressed or diminished. The bowels are sometimes loose, but constipation is the usual condition. The appetite is uncertain; sometimes it is impaired, but more frequently it is abnormally large. Not infrequently the sense of taste is perverted, and the patient suspects the presence of poison in her food, and persistently refuses it. The breath is often offensive in odour. Sometimes the mental excitement does not reveal itself in language, and the patient may be obstinately taciturn from the commencement. But there is usually a great increase of loquacity, gradually increasing from the beginning, and passing into incoherent raving. Sudden impulsive acts of violence frequently manifest themselves in this disorder, and in these the patient often attempts to destroy herself, her child, or persons for whom she has usually the most affectionate regard. She generally appears to be dissatisfied with those in attendance on her, and often entertains delusions as to their identity. In many cases the mental condition bears a strong resemblance to that of delirium tremens, especially when the patient has undergone privations, or has been intemperate during pregnancy.

DIAGNOSIS.—The only conditions for which puerperal insanity may be mistaken are the typhoid delirium of puerperal fever or pyæmia; and the violent excitement frequently symptomatic of meningitis. In these cases the febrile condition precedes the development of the delirium, while in puerperal mania the mental symptoms show themselves from the first. In meningitis the pupils are generally contracted, and the headache is peculiarly intense; while in

puerperal mania the pupils are usually dilated, and the headache is not a very prominent symptom.

Prognosis.—According to the published statistics of this disease, recovery may be expected in about 70 per cent. of the cases, and a fatal termination need not be anticipated in more than 6 per cent. But as these figures are in a great measure obtained from asylum statistics, and other sources in which only the severer and more persistent forms have been taken into account, it may be fairly assumed that the true estimate would be much more favourable. The duration of the insanity may vary from a few days to a year, after which time the proportion of recoveries becomes extremely small. The great proportion of recoveries takes place during the first six months. The most favourable symptoms, in addition to amelioration of the mental symptoms, are increase of bodily weight, and restoration of the catamenia.

Treatment.—The transitory mania which sometimes accompanies the severer pains of labour does not require special treatment; but anaesthetics may be given as a preventive measure in cases where there is a known liability to such excitement. Special care ought also to be taken after such attacks, until the strength is fully restored, to avoid injury by premature bodily exertion, unnecessary social intercourse, disquieting news, or any kind of mental or moral strain. In the treatment of the graver form of puerperal mania, the chief objects are to remove all sources of irritation, to restore the patient's strength, and to obtain repose. If there is any accumulation of feces, a smart purgative should be at once administered. If the lochial discharge is scanty, an injection of warm water, containing carbolic acid or some other antiseptic remedy, should be given *per vaginam*. The condition of the bladder should be ascertained, and this organ should be relieved, if necessary; care should also be taken not to allow the breasts to be over-distended. In those cases in which violent excitement does not come on suddenly, an attack may sometimes be warded off or cut short by relieving the sleeplessness which is one of the early symptoms. As a hypnotic about thirty grains of chloral is the best. Opium ought to be avoided, and hyoscyamus and belladonna cannot be relied on. In every case the patient should receive from the first as much light and nourishing food as her digestive powers can properly bear; for it must always be remembered that we have to deal with a condition of anaemia. Both in the first stage, and when the disease is more advanced, everything must be done to promote tranquillity. The room should be darkened, and stillness maintained as far as possible, for the attention of the patient is very easily excited, and both vision and hearing are preternaturally acute. Constant supervision is necessary, however, on account of the tendency to sudden impulsive violence; and the patient should see her infant as seldom as possible. After the menial condition has fairly declared itself, the child should be removed altogether, as its presence is sometimes productive of great excitement in the patient, and must always be regarded as attended with risk to itself. In cases where the excitement is somewhat of a hysterical

character, bromide of potassium, given in twenty-grain doses at intervals of four hours, may produce good results. Cooling applications to the head sometimes soothe irritation, and induce sleep. Digitalis in small doses, and warm baths, have proved useful. Alcoholic stimulants should generally be given with the food; their effects being carefully watched, and the quantity varied accordingly. Bleeding and every kind of depletion should be avoided. The nursing and attendance should, if possible, be entirely entrusted to strangers, and the patient should not be permitted to see any members of her family. It will sometimes be necessary, especially in the case of poor persons, to resort to asylum treatment; but this ought not to be done if it can be avoided; and with patients in good circumstances it ought never to be necessary in the acute stage of the disease. When the disease becomes chronic, tonics, such as quinine and iron, ought to be given, and a plentiful supply of nourishment should then, as all through the illness, be carefully administered. Patients liable to this disorder should not be allowed without consideration to nurse their children.

The *manus* of lactation is symptomatic of causes which come into play after the puerperal period, and it ought perhaps to be looked on as symptomatic merely of prolonged anaemia. Acute maniacal symptoms of short duration may occur; but the characteristic condition is melancholia, ushered in by headache, tinnitus aurium, flashes of light before the eyes, and other signs of debility. A suicidal tendency sometimes appears. The treatment required is to wean the child, and generally to save and increase the strength of the patient. The prognosis is favourable in the majority of cases. JOHN SIBBALD.

14. Syphilitic Insanity.—Among the results of constitutional syphilis, affections of the nervous system are not uncommon; and when the disease affects the brain, the mental symptoms that arise are found in the majority of cases to present a marked similarity in their character. In such cases the mental disorder is generally preceded, as in so many forms of insanity, by distressing sleeplessness. This is followed gradually by increasing depression of mind. Religious anxiety of a peculiarly hopeless character frequently shows itself. Exaggerated self-accusings are earnestly uttered by those who have previously been unusually callous as to the results of their actions. Hypochondriacal delusions are not uncommon, and are frequently associated, in the mind of the patient, with the fact of the syphilitic infection. The feeling of alarm which accompanies these symptoms sometimes develops into a violent excitement, which may be called maniacal. If the symptoms be associated with any of the ordinary signs of syphilitic poisoning—the dry, scaly skin, and the sallow lean face; and especially if any of the characteristic eruptions are present, the mental disease may be expected to yield to treatment by mercurials and iodide of potassium. The mental symptoms which have been here described seem to occur without the existence of any important structural lesions in the encephalon. The development of gummy products within the cranium is frequently

swined by symptoms similar to those of general paralysis. Headache of very persistent character, giddiness, vertigo, and epileptoid fits occur, accompanied at first with mental depression. During the progress of the disease attacks of acute delirium are not unusual. Sometimes extravagant delusions, such as are frequent in general paralysis, are exhibited; but generally the progress of the disease is characterised by a gradual falling into dementia. The prognosis in such cases must be regarded as unfavourable, but considerable improvement frequently follows the administration of antisyphilitic remedies.

JOHN SIBBALD.

INSECT PARASITES.—Insect parasites are of two kinds, external and internal. The former are described under several affections of the skin (*see* **PIMICULI**; **SCABIES**; &c.); the latter are classed with the entozoa. *See* **ESTRUS**; **CHIGOS**; and **DEMODOX**.

INSENSIBILITY (*in*, not, and *sensio*, I perceive).—This word signifies either loss of consciousness; or merely loss of sensation in a part. *See* **CONSCIOUSNESS**, **Disorders of**, and **SENSATION**, **Disorders of**.

INSOLATIO (*in*, in, and *sol*, the sun).—A synonym for sun-stroke (*see* **SUNSTROKE**). *Insolation* is also used to designate a method of treatment, which consists in exposing the patient to the rays of the sun.

INSOMNIA (*in*, not, and *somnus*, sleep). Want of sleep, or sleeplessness. *See* **SLEEP**, **Disorders of**.

INSPECTION (*inspicio*, I look upon).—The technical name for the examination of a patient by the sense of sight. *See* **PHYSICAL EXAMINATION**.

INSTILLATION (*in*, into, and *stilla*, a drop).—The method of applying remedies to a part in the form of drops. *Instillation* is chiefly employed in connection with the eye.

INSUFFICIENCY (*in*, not, and *sufficio*, I am sufficient).—A synonym for incompetence. *See* **INCOMPETENCE**.

INSUFFLATION (*in*, into, and *sufflo*, I blow).—This term is used in the same sense as *inflation* (*see* **INFLATION**). It is also a name given to a method of applying remedies in the form of powder to the throat and respiratory passages, by blowing them through a tube into these parts. *See* **INHALATIONS**, **Therapeutic Uses of**.

INTEGUMENTS, **Diseases of**. *See* **SKIN**, **Diseases of**.

INTELLECTUAL INSANITY. *See* **INSANITY**.

• **INTEMPERANCE**, **Effects of**. *See* **ALCOHOLISM**; and **DISEASE**, **Causes of**.

INTERCOSTAL NEURALGIA.—Any of the dorsal nerves may be the seat of neuralgia, not differing materially in its symptoms from neuralgia affecting other mixed nerves, but especially important from a diagnostic point of view. The pains are paroxysmal; usually affect the region of distribution of the anterior division of

one or two of the dorsal nerves; and are confined to one side, most frequently the left.

ÆTIOLOGY.—The female sex, neuritic heritage, and weak general health predispose to intercostal neuralgia. As determining causes may be mentioned blows; the action of cold; local injury to the nerves from the growth of thoracic aneurism; and disease of the vertebrae. Exhaustion from oversuckling, menorrhagia, or leucorrhœa, irritation from cracked nipples; and pregnancy are all occasional but important causes of this form of neuralgia. The pain met with in the chest in early cases of phthisis is not unfrequently due to intercostal neuralgia.

SYMPTOMS.—Pain is complained of at some part of one side of the thorax or abdomen, most often in the region innervated by the sixth, seventh, eighth, or ninth intercostal nerves, and much more frequently in the front or side than behind. It is occasionally found in the axilla and inner side of the arm. The pain may be intermittent, occurring in paroxysms, varying in number from a recurrence every few minutes to only two or three such during the twenty-four hours; or there may be persistent pain of a dull character, interrupted at varying intervals by darts of a very sharp kind which may sometimes be referred with precision to the course of the neighbouring nerve. The pain is described as 'tearing,' or resembling such injuries as a 'stab of a knife,' or 'loring with a red-hot iron.' The acts of coughing or sneezing, as well as any rapid movements of the body, are apt to increase the distress, but the pain is also independent of these disturbances, and will attack without any such provocation. The pain is sometimes more of a wearing than acute character, and the rest will often be destroyed by it. Painful points are sometimes to be discovered in the following situations:—1. Over a spinous process corresponding to the emergence of the affected dorsal nerve from the intervertebral foramen. 2. At the side of the chest or abdomen, where the lateral branch becomes subcutaneous. 3. Near the sternum or at the margin of the rectus abdominalis muscle, at any part down to the pubes, where the termination of the nerve supplies the skin. The skin in the neighbourhood of the tender points is sometimes so hyperæsthetic that the pressure of the clothes is painful. In epileptics and other highly neurotic patients, intercostal neuralgia is often associated with palpitation of the heart, and the pain is usually referred in a vague manner to that organ. Close examination will show that it is in the chest-wall, and tender points may generally be discovered. The affection is not accompanied by fever. The paroxysms of pain may produce fainting and vomiting. They often cause dyspnoea, with an anxious expression of face, from the inability to draw a full breath without starting the pain.

COMPLICATIONS.—Intercostal neuralgia is sometimes accompanied by herpes zoster. The pain usually precedes the appearance of the eruption, but it is occasionally coincident only, and sometimes comes after it; more often than not it outlasts the eruption, it may be for a long period. In certain cases actual pain lasts but a few days, but is succeeded by an intolerable itching, which is described as being under, not in the skin. This

sensation is said to be felt less in walking than when at rest.

Not unfrequently neuralgia of some other nerve, either at a distance, as the fifth, or anatomically near, as the brachial plexus, occurs as a complication of intercostal neuralgia. This is especially likely in cases happening in the period of bodily decay. It is then too, that the affection may occasionally be accompanied by attacks of angina pectoris.

DIAGNOSIS.—Absence of pyrexia, as shown by the use of the thermometer, the intermittence of pain, and its occurrence irrespective of respiratory movements, although liable to be precipitated by them; and the results of physical examination, serve to distinguish intercostal neuralgia from pleurisy, a condition with which, on account of resemblance in the stabbing character of the pain, it is very apt to be confounded.

From muscular rheumatism it may be discriminated by the presence of the small and characteristic tender points, tenderness of the spinous processes on pressure; and by the pain being found to be not dependent upon movements. The same features serve to distinguish it from myalgia, especially that form which often comes from long-continued use in an unaccustomed manner of some muscle attached to the ribs, as when a person unused to carpentering handles the saw energetically for a long time.

Physical examination and the presence of pyrexia, will preserve from the error of confounding the dull pain often noted in pneumonia with that of intercostal neuralgia.

Pains of a stabbing, plunging, or electric-shock-like character are often experienced in the intercostal spaces in the course of locomotor ataxia, and it is important not to confound this disease with a simple attack of intercostal neuralgia. The distinguishing points are the occurrence of similar pains coincidently or alternately in other parts of the body, especially in the lower extremities; the absence of patellar tendon reflex; and the characteristic gait (if present)—all which mark locomotor ataxia.

PROGNOSIS.—As in the case of other forms of neuralgia, that of the intercostal nerve can hardly be said to be attended with danger, though it must be allowed that in some very rare instances the severity of the pain appears to have actually destroyed life. It is apt, however, to be of troublesome duration, lasting for periods of weeks or months, and liable to recurrence.

TREATMENT.—Search should be made in other branches of the same nerve, and in the distribution of neighbouring nerves, for any source of irritation which it is possible to remove. Constipation of the bowels should be treated by 3 grains of pilula hydrargyri, followed by some Friedrichshall or Hunyadi János water, repeated for two or three days. Quinine should be given in doses of from five to ten grains twice a day; and if there should be a state of anæmia, steel should be added. Exposure to cold and damp must be avoided; whilst the surroundings generally should be favourable to improving the nutrition and tone. If the pain be very acute, and sleep prevented, morphia may be injected hypodermically in the neighbourhood of the affected nerve, commencing with a dose of an eighth of a grain and in-

creasing this, if necessary, to a quarter of a grain in the twenty-four hours. This dose should not be repeated, however; and it is better to be satisfied with a repetition of the smaller dose, if required. Small blisters (size of half-crown) may be applied to the neighbourhood of the spinal column, near the point of emergence of the affected nerve, one succeeding another as it fails. The continuous voltaic current, from about 10 to 20 cells, Leclanché or Stöhrer, may be applied, one sponge on the spine and the other upon the painful point, in turn. There is no better application than collodion flexile for the herpes zoster which sometimes complicates intercostal neuralgia. See NEURALGIA.

T. BURNARD.

INTERLOBULAE (*inter*, between, and *lobulus*, a little lobe).—Situated in the tissue between the lobules of any organ. A good illustration is *interlobular emphysema*, in which air occupies the parts between the lobules of the lungs.

INTERMITTENT (*intermittit*, I leave off for a time).—A temporary cessation or suspension, either of a function, for example, of the action of the heart, when the pulse is said to *intermit*, or of a disease, such as neuralgia or ague, when the symptoms cease for a certain time. See PULSE, and INTERMITTENT FEVER.

INTERMITTENT FEVER.—SYNON.: Ague, Fr. *Fèvre intermittente*; Ger. *Kaltes Fieber*.

DEFINITION.—A fever of malarial origin, characterised by the sudden rise of temperature during the paroxysm, by the equally sudden fall at its termination, and by the regularity of the times of accession and apyrexia.

ÆTIOLGY. Intermittent fever belongs to the class of malarial or paroxysmal fevers. It is the most typical, and the most common of the class. The human system once subjected to the phenomena of a regular attack of ague in any of its forms, is for the remainder of the life of the person so affected liable to a repetition of the attack, without his necessarily having been exposed afresh to the action of its cause. This tendency is very commonly shown in those who, after long residence in hot and malarial climates, are exposed to the influence of cold, and especially easterly winds, on their return to temperate climates in the spring time of the year. The more the person has suffered from the blood-changes and visceral degenerations described in the article MALARIA, the more prone is he to such recurring attacks.

ANATOMICAL CHARACTERS.—In the article MALARIA the pathology of intermittent fever is fully discussed, including its probable dependence on the presence of the *Bacillus malarie* in the body. The spleen is enlarged, and in pernicious agues proving rapidly fatal, it is found in a state of softening, often reduced to a state of deeply pigmented pulp. Death is common in malarious countries from rupture of the spleen, the result of blows or kicks, often of no great severity. The liver is usually found somewhat congested and pigmented, and in cases of long standing it enlarges like the spleen, with

the same increase in the connective tissue. In the algidæ cases hereafter described, when blood is driven in large quantity into the abdominal viscera, the digestive mucous membrane of the stomach and duodenum is congested and softened. The heart is invariably soft and flaccid, pale, sometimes of a dirty yellowish colour—degenerative changes induced by the combined action of diseased blood and high temperature.

Blood-changes.—Blood-changes sometimes take place both in intermittent and remittent fevers with astonishing rapidity. Army medical officers serving in the Mauritius during the epidemics of malarial fever which prevailed there some years ago, noted that the sufferers were often reduced to a state of complete anæmia in a few hours; the same is the case in Algeria (see MALARIA). In such cases dropsical affections supervene, often rapidly, and military medical officers there record cases 'proving suddenly fatal from œdema of the glottis.' The blood is changed before any of the usual symptoms of an attack are present—it becomes dark in colour, the serum which separates has a dark brown colour, and when exposed to the air, the coagulium, which is large and loose, does not assume its usual bright-red colour. The white corpuscles are immensely increased in number, and the red corpuscles do not evince their usual tendency to run together in rouleaux.

State of the urine.—The urine contains a large amount of free acid, and retains a highly acid reaction for many days in the hottest weather. In the intervals it is often alkaline. When the paroxysms cease, the watery part of the urine diminishes, and it assumes a deep orange colour, depositing also an abundant sediment of urate of ammonia. This change is often observed by intelligent patients, who learn to appreciate its favourable significance. The late Dr Parkes has shown that at the first elevation of temperature the uræa increases, this lasts during the cold and hot stages; then it decreases, falling below the healthy average. Colin and other French authors note the enormous excretion of uræa in malarial fevers both in Italy and Algeria.

Symptoms.—Three forms of ague have long been recognised, namely, the *quotidian*, which recurs in twenty-four hours, the *tertian* in forty-eight hours, and the *quartan* in seventy hours. The term *double tertian* is used when the paroxysm recurs regularly on alternate days, the attacks being alike in severity and duration. Other more rare forms of the irregular type have been described, as the *treple tertian*, with two paroxysms in one day, and one the next, the *double quartan*, with a regular fit one day, a slight one the next, and a complete intermission on the third day. The *quotidian* is the most common; the *quartan* the rarest of all—a rule which seems to hold good wherever malarial fevers prevail. The *quartan* type has been noted from early times for the tenacity with which it clings to its victims.

Prenatal symptoms.—These are much the same as in all febrile disorders, namely pain in the back and lower extremities, languor, lassitude, gastric irritation, loss of appetite, nausea, and sometimes vomiting; with occasionally frequent calls to micturate, the urine being pale and highly acid. Then follow in succession the three

stages, the *cold*, the *hot*, and the *sweating*; succeeded by what is technically known as the *intercal* or *apyrexial* period, which lasts for a number of hours, varying according to the type of the disease.

Cold stage.—The patient experiences a sense of coldness in the back, then rigors set in, at first faintly, becoming quickly more distinct, until the teeth clatter, and the patient feels cold all over, and demands to have clothes heaped on him; the skin shrivels, the nails become blue, and he experiences a sensation of intense discomfort. This feeling of cold is, however, only a 'subjective symptom' for if a clinical thermometer be placed in the mouth or rectum, even before distinct rigors set in, it will indicate a rise in the temperature of from two to three degrees. The skin, from contraction of the superficial vessels, is indeed colder than natural, but from the first the temperature of the blood is above the normal. The phenomena of the cold stage are gastric irritation, a foul tongue, a rapid pulse, and quickened respiration, with a feeling of coldness not confirmed by the thermometer.

Hot stage.—As this sets in, the patient grows warm all over, the face flushes, the pulse rises in frequency and volume, the skin grows hot, and the patient becomes restless, seeking ease to his aching head, back, and limbs in frequent change of posture. The tongue in this stage is usually dry, often bile-tinted, and the bowels are constipated.

Sweating stage.—At first beads of perspiration appear on the brow and face, and the limbs become moist, and soon, to the immense relief of the patient, his whole body sweats freely, the temperature begins to decline, and the paroxysm is at an end. The average duration of the paroxysm is from five to six hours, but in severe cases it may last for twelve hours. When sufferers have been exposed to malaria in such places as the mangrove swamps of Africa, 'they will be reminded of what their systems have imbibed in the way of surroundings by the sickly scent of the swamps thrown off in the secretion through the skin' (Waller). Both officers and soldiers who came under the cure of the writer on their return from the late expedition to the Gold Coast, observed the same fact in their own persons, some were severely nauseated by the unpleasant smell, recalling the stench of the places where the poison was probably taken into their systems.

Temperature.—The rapidity with which the temperature in ague rises to 104°, 106°, and sometimes 107° Fahr, and the equally sudden manner in which it falls when the sweating stage begins, is a very notable and characteristic fact of great diagnostic value. According to Wunderlich, nothing like this is to be seen in any other disease, with the exception of cases of relapse in typhoid, the febrile paroxysms in acute tuberculosis, and pyæmia. As soon as the sweating stage begins, the temperature declines, at first slowly, then as rapidly as it rose; when the desferescence is complete, it will be found one or two points of a degree below the normal, where it remains during the period of *apyrexia*. If the paroxysms be cut short by quinine, we may still detect at the hour of expected attack a distinct

rise in the temperature, although none of the other symptoms of a paroxysm may occur, and the patient may be hardly sensible of it.

Pernicious ague.—This term is much used both by French and Italian authors, who apply it to cases both of intermittent and remittent fevers, in which certain symptoms are developed, such as delirium, coma, an algide condition; in a word, any serious complication placing the life of the patient in peril. So far at least as intermittent fever is concerned, this pernicious form appears to be more common in the intensely malarious regions of Italy than in India. Such was the experience of the writer, in whose large sphere of observation such grave complications were almost entirely confined to the worst forms of remittent fever, contracted in places notoriously dangerous. The writer is strongly impressed with the belief that the 'pernicious' symptoms, the mental incoherence and delirium, the coma, and the 'algide condition' so much dwelt on by some Italian physicians of the old school, were often the result, not so much of the disease, as of the lowering treatment to which they subjected their patients.

The algide form of 'pernicious' intermittent is sometimes described by writers on the diseases of India as 'ague of adynamic type,' and it was frequently seen and well described by the French military surgeons both in Algeria and in Rome, during the long occupation of that city by the French army. The surface is cold, but, unlike the cold stage of an ordinary ague, the patient is unconscious of the low temperature of the surface. The internal temperature is high, and of this he is aware. There is an immense accumulation of blood in the abdominal viscera, with great thirst. The expression of the patient is tranquil, and his intelligence is intact. 'Il se sent mourir,' says Maillot, 'et l'abattement est tel qu'il se complaint dans cet état de repos; son physionomie est sans mobilité; l'impassibilité la plus grande est peinte sur le visage.' (Maillot, Colin.)

Complications.—Intermittents may be complicated by attacks of various diseases of greater or less severity—attacks often governed by climatic causes, by the habits of the individual patient, or by the fact that he has suffered from one or other of such diseases on previous occasions, such as pneumonia, bronchitis, asthma, dysentery, diarrhoea, or epilepsy. It is an old observation that the last-named disease, even in so-called 'confirmed epileptics,' sometimes disappears when the victim becomes the subject of an attack of ague. One very striking example of this kind the writer has seen.

Pneumonia is certainly the most formidable complication met with in intermittent fever. Invalids returning from India or from other hot and malarial climates to high latitudes, unless they are carefully protected by suitable clothing, are prone to suffer from this disease. The rapidity with which consolidation of the lungs takes place in such cases is very remarkable. It is not an uncommon thing to see five or six cases of this kind out of one party of invalids landed at Hvalley from India, if, on entering the Channel, they have been exposed to cold weather. The pneumonia is generally double, and recovery is rare, the patients either sinking at once, or

dying after a longer or shorter illness from pneumonic phthisis. Pneumonia of this type is a common and fatal disease among the malarial-poisoned civil population of Rome during the winter months; and the French military surgeons record its prevalence in the French garrison there at the same season, and also among malarial invalids sent back to France both from Algeria and Rome (*Recueil des Mémoires Méd. Mil.* t. ii. 2^e Série, p. 268). When pneumonia occurs as a complication of any form of malarial fever, it is one of the gravest import. There is no difficulty in making the diagnosis by the ordinary means.

Diagnosis.—An ordinary intermittent presents no difficulties. The well-marked nature of the paroxysms; the sudden rise of temperature and its equally sudden decline, the splenic enlargement; the discolouration of the skin, the urinary changes described above; together with considerations relating to the place where the disease was contracted; and, above all, the therapeutic test, that is, the power of quinine in preventing the recurrence of the attacks, ought to clear up all doubts.

Prognosis.—This, in ordinary agues, so far as immediate danger is concerned, is highly favourable; death from uncomplicated ague is very rare. The direct mortality from ague, at all events among the European races affected by it, is small; the indirect mortality from the malarial cachexia, occurring either *per se* or as a complication of other diseases, is very great. In complicated or so-called pernicious agues, the prognosis will depend on the extent to which important organs are involved—cerebral, pulmonary, or gastric, much on the stage the disease has reached before the patient comes under treatment, and much, very much, on the nature of that treatment.

Treatment.—Keeping in view the fact that every paroxysm of intermittent fever, particularly in a hot climate, is a step, however short, on the road to the cachectic condition described above and in the article on MALARIA, the importance of breaking the recurrence of the paroxysms will be apparent. This, then, is the first indication of treatment, the second is hardly less important, namely, to improve the condition of the blood, and by judicious treatment—therapeutic, dietetic, and climatic—to prevent further degeneration of organs, and, so far as may be, to restore affected tissues to their normal condition.

If, as the writer firmly believes, there be such a thing as a specific disease, intermittent fever is specific. Like all such, it has a certain definite series of phenomena to pass through, which we may assume to be needful for the purpose of destroying, altering, or in some way expelling the poison, or at least such portion of it as may at the time be acting on the system. There is no drug known to science capable of arresting the stages of a true malarial fever once it has entered on the first or cold stage. This doctrine, as Sir William Jenner has admirably stated it in his *Address on the Etiology of Acute Specific Diseases*, has been taught by the writer, as regards malarial fevers and cholera, in his lectures at Netley for the last twenty years. There is little, therefore, to be said as to the treatment of the stages of ague; they must take their course, the only interference being to supply the patient with the

warm covering so much desired during the cold stage; if this be protracted unduly, to give him draughts of warm tea; and should symptoms of collapse appear in any of the more 'pernicious' forms at the end of the hot stage, to administer such restoratives and stimulants as the case may demand. Excepting in cases where the stomach is oppressed by a recently taken meal, the time-honoured practice of administering an emetic may be safely omitted. The lamented traveller Livingstone, whose experience of malarial fevers was immense, began the treatment of nearly all cases with the following combination: Itchin of jalap and of rhubarb, from 6 to 8 grains, with 4 grains of calomel and a like quantity of quinine. According to the great traveller and his hardly less experienced companion, the Rev. Horace Waller, this combination was found very efficacious as the commencement of treatment both in intermittent and remittent fever. In Livingstone's camp his pills were known as 'rousters,' and as such were at once administered to men who, 'from promonitory symptoms, became idle and lethargic.' In about five hours copious dark coloured motions followed, if these were delayed, recourse was had to a brisk purgative enema. Quinine was then given in 4-grain doses every four hours, until twelve grains were administered in the twelve hours succeeding the purgative medicine. Livingstone and his followers deemed any other mode of dealing with the fevers of Africa to be 'more trifling.' Common sense points to the necessity of caution in the use of such active purging in men much debilitated by disease or climate, or both, or when the patients are delicate women, or Asiatics, often calling for an delicate handling. It is hardly necessary to add that this sharp treatment is not applicable to those who are labouring, or have previously laboured under dysentery, or any other form of bowel-complaint.

In the 'interval,' energetic efforts must be made to bring the patient under the influence of quinine. At once the most effective and the most economical plan is to administer quinine, in solution, in a ten-grain dose at the end of the sweating stage, and to repeat it in from four to six hours. At least a scruple of the remedy should be given during the interval. If obstinate vomiting interferes with the retention of the quinine, which will rarely happen if the bowels have been well relieved, the quinine must be administered either by enema or by the hypodermic method. The first plan is very efficacious, and is safe; the latter is the most effective, but is not without risk of inconvenience from troublesome ulceration round the site of injection, if a mineral acid has been used to dissolve the quinine: this in urgent circumstances, such as in pernicious agues dangerous to life, or in remittents (as will be explained under the head of that type of fever), might be disregarded were it not that tetanus followed the operation in five cases in one year in the Bengal Presidency, all of them proving fatal. In the face of such a fact, this operation, trivial as it seems, should not be performed on light grounds. The neutral sulphate of quinine, which dissolves freely in water at a temperature of 90° F., does not, so far as the writer's experience goes, cause ulceration. The

syringe used for this purpose should be a little larger than that for operations with morphia, and should have a platinum hollow needle.

Quinine, in one or other of the methods advised, should be used until the paroxysms are broken. The remedy should be continued daily, so long as the clinical thermometer indicates a rise in temperature at the time of expected attack, even if there be no sign of a regular cold stage; and within a lunar month from the time of first attack, the patient should be again brought under the influence of quinine for some days. In pernicious agues, or in cases where complications arise, it is in a high degree dangerous to pause in the administration of quinine to use remedies of a depressing kind for this or that set of symptoms. Those who so act will have little success in practice until taught by bitter experience the danger of departing from the golden rule of trusting to quinine. In this way, epilepsy, pneumonia, asthma, bronchitis may have to be met, aided by stimulation of the skin, support from proper food, and stimulants when called for. For many years the writer has urged this doctrine on the attention of young practitioners, and he is glad to see that it is even more strongly insisted on by Trousseau in his well-known lectures.

It is in such cases, and in grave remittents, that the *Tinctura Warburgi* has been found so useful as to warrant a strong recommendation. The active ingredient in this tincture is quinine, in combination with a variety of aromatic drugs, which either are now, or were formerly official. It is the most powerful sudorific known, and has been found in the writer's hands, and in the practice of many medical officers in Southern India, a remedy of great power in all malarial fevers. After opening the bowels, half an ounce of tincture is administered, undiluted, all drink being withheld: a second dose is given in three hours. It soon produces free action of the skin, the perspiration often having an aromatic odour. It is rare to see another paroxysm follow the use of the tincture. In adynamic cases it should be used in smaller doses, and with some caution, lest its excessive sudorific action should be too depressing.

Substitutes for quinine.—The officers in charge of the Government cinchona plantations in India now prepare from the red cinchona bark, by a very simple and economical process, a preparation known as 'cinchona alkaloid,' which, in somewhat larger doses than quinine, is found to be effectual in checking malarial fever, but this preparation, although very cheap, has fallen into disrepute from the distressing nausea, and even vomiting, it often causes.

Salicylic acid is now largely used as an antipyretic.

¹ Dr. Warburg has communicated to the writer the formula for the preparation of this tincture, which as Dr. Warburg's name was published in the *Lancet*, and *Medical Times and Gazette*, (see *Medical Times and Gazette*, 1878, vol. II. page 540.) As stated in the text, quinine proved to be the active ingredient, in combination with a number of aromatic drugs common to ancient and modern pharmacy. It is consistent with the writer's knowledge that this tincture has maintained its high reputation in the treatment of malarial fevers of the most dangerous type, in the hands of Colonel Gordon, in the pestiferous regions traversed by him and his officers while carrying out the policy of the Khedive of Egypt along the head-waters of the Nile.

Arsenic has been used for ages, particularly in the East, in the treatment of agues. There is no doubt that it possesses considerable power as a so-called antiperiodic. The French military surgeons, who are obliged to study economy, use it largely, and in doses much larger than are commonly given by British practitioners. They seek, as Boudin expresses it, to oppose an arsenical to a malarial diathesis. In the low-aches and other neuralgic sequelae of malarial fever it is an effective remedy, either alone or in combination with quinine. The alkaline sulphites, so much lauded by Professor Polli, have hitherto disappointed the expectations of British medical officers who have tried them. In the late epidemic outbreak of malarial fever in the Mauritius they were found useless. The sulphate of cinchonine in scruple doses is much praised by Dr. Paul Turner. Bileline was largely tried by the writer in India, and found to be inert. Of late, various preparations of *Eucalyptus globulus*, the blue gum tree of Australia, have been much praised in the cure of ague, and more particularly in the treatment of its sequelae. The writer is inclined to fear that this remedy, like many others, has been unduly vaunted. It certainly is often useful in the malarial cachexia, with occasional attacks of ague, but in the acute forms of the disease it is, in the experience of the writer, far below quinine. The best form is that of tincture. Both in France and Germany it is much used for the reduction of enlarged spleens.

Diet.—This should be nutritious and easy of digestion. Dr. Cornish has pointed out how much the mortality from malarial fevers is increased amongst the natives of India by 'starvation treatment.'

Treatment of malarial cachexia.—On the first signs of this condition appearing, the sufferer should be sent to a non-malarial climate. If by sea-voyage, care must be taken so to regulate the diet as to avoid the risk of ingrafting the scorbatic on the malarial cachexia. Remembering also the danger of exposure to cold insisted on already, scrupulous attention to clothing is a point of cardinal importance. According to the writer's experience, one of the most effective means of reviving the action of the skin, improving the condition of the blood, and restoring the spleen and liver to a more healthy condition, is to send those whose circumstances admit of it to Carlsbad or Homburg, where, under proper local medical advice, they may drink the waters and use the baths. The good effects of this treatment are often very marked and lasting. It should be supplemented by a course of the syrup of the triple phosphates of iron, quinine, and strychnia, in half-drachm doses three times a day; which after a time should give way to iron in some more direct form. The Carlsbad water, in combination with that of Friedrichshall, if continued for a sufficient length of time, is often most useful in improving the condition of the abdominal organs, even when the patient can only use them in this country; and the action of the skin may be stimulated with profit by the occasional use of a Turkish bath, or by a wet sheet packing. The writer has long used the ointment of the biniodide of mercury in reducing enlarged glands, and often with great success. The strength of the ointment is 13 grains to an ounce

of lard. Of this a piece as large as a walnut is to be well rubbed in before a good fire. The process is repeated on the afternoon of the same day, and again, if need be, in a fortnight. If ordinary care be taken to watch the effects, and not to use the remedy too often, no ill consequences need be feared. The writer has in this way again and again reduced spleens, extending even into the pelvis, to almost normal dimensions, without producing any of the inconveniences either of the mercurial or iodine ingredients of the ointment.

It is a point of great importance that patients should be placed under the most favourable hygienic conditions, and breathe the purest air available.

INTERNAL EAR, Diseases of. See EAR, Diseases of.

INTERSTITIAL (*inter*, between, and *sto*, I stand)—Relating to the interstices of an organ. The term is applied in physiology to the tissue which exists between the proper elements of any structure, namely, some form of connective tissue. In pathology the word is used in connection with *absorption*, when a part is gradually removed without any obvious breaking off; and also to indicate the implication of the interstitial tissues in morbid processes, or their infiltration with morbid products, as *interstitial pneumonia*, *interstitial hepatitis*, &c.

INTERTRIGO (*inter*, between, and *tero*, I rub).—**DEFINITION**—A slight inflammation of the skin occurring in the hollows of folds of the integument or joints, where two surfaces lie in contact with each other.

ÆTIOLOGY.—The cause of intertrigo is not, as might be implied by its name, friction alone; but rather moisture and heat associated with contact and pressure, acting on a sensitive skin. In certain situations the amount of inflammation is liable to be aggravated by the addition of irritant discharges, such as excessive perspiration, urine, and fecal matter.

Intertrigo is common in infants, in whom it is favoured by abundance of integument, and sensitiveness of skin. For a similar reason it is met with in corpulent persons, but it is not wanting in the emaciated, when there exists a tendency to eczema, or an eczematous diathesis. In infants it is seen in the perineum, extending from the anal fossa behind to the groins in front, and likewise in any other of the deep folds of the integument. Among adults, in addition to these situations it occurs in the axillae, in the groove beneath the mamma, and in the flexures of joints.

DESCRIPTION.—The term intertrigo points to a rubbing together or chafing, fretting, or galling of the skin by friction, and no doubt friction may have some share in producing the inflammation; but it is also certain that intertrigo results most frequently from irritation caused by the heat and moisture of the part. Intertrigo has been adopted as an erythema under the name of *erythema intertrigo*, but it very rarely remains at the erythematous stage, having a natural tendency to run on to exudation with the discharge of a mucopurulent fluid, and to be further complicated with excoriations and chaps. In this condition it becomes an eczema and is

very properly treated as such. Indeed, it is more consistent with the genius of modern dermatology to consider it, even from the beginning, as an eczema, under the name of *eczema erythematodesum*.

Prognosis.—The prognosis of this affection is favourable as to cure, but uncertain as to time, and in adults it is very apt to degenerate into chronic eczemas.

Treatment.—The removal of the cause is the first indication to be attended to in the treatment of intertrigo. This may be effected by careful ablution with soap. The part should then be kept as dry and cool as possible, and dusted with fuller's earth, or any unirritating desiccative powder. Where powder is unavailable, a lotion of lime-water impregnated with oxide of zinc will be found useful, and if this should prove irritating, zinc ointment, with the addition of a drachm of spirits of wine to the ounce, should be kept constantly applied. Where there is much exudation, it is desirable, as in eczema, to avoid ablution, and confine the treatment to wiping with a soft cloth previously to each repetition of the zinc ointment. Constitutional symptoms are rarely present in intertrigo, but should such arise, the indications to be considered are regulation of the digestive organs and associated functions; a suitable diet, and tonic regimen.

ERASMUS WILSON.

INTESTINAL OBSTRUCTION.—SYNON.: *Ileus*; Fr. *Occlusion intestinale*, (ier *Darmverschlingung*).

DEFINITION.—Under this term are included all those cases in which the contents of the intestinal canal are obstructed in their onward passage, by causes or conditions occurring within the abdomen or pelvis. Cases in which obstruction is due to causes or conditions affecting protruding or protruded bowel are included under the head of *HERNIA*.

GENERAL REMARKS.—The subject of intestinal obstruction will be best treated by first discussing the condition in general, and afterwards referring to its various pathological causes under separate and distinct heads.

FREQUENCY.—The comparative frequency with which intestinal obstruction occurs is difficult to estimate. It is by no means a common affection, though less rare, perhaps, than is sometimes supposed or asserted. It is always fraught with danger, and in a very large proportion of cases more or less speedily proves fatal. Brinton estimates 1 out of every 280 deaths from all causes to be due to some form or other of intestinal obstruction. Leichtenstern gives 1 out of every 300 to 500. Brinton's estimate, founded on the results of 12,000 post-mortem examinations, is probably somewhat too high, inasmuch as a larger proportion of cases of intestinal obstruction are likely to have been inspected than of cases of more common and less obscure affections.

ÆTIOLOGY AND PATHOLOGY.—Most forms of intestinal obstruction are more often met with in the male than in the female subject. Out of a total of 1,806 sufferers, 1,018 were males and 788 females. But women are more liable than men to suffer from certain forms, as, for example, those which depend upon impaction of gall-

stones or fecal matter; upon compression of the intestine by tumours or displaced viscera; or upon constrictions by peritoneal or other adhesions. Some forms, especially intussusception and volvulus, most frequently occur during infancy or childhood; others, as strictures, as comparatively advanced periods of life.

The causes, or anatomico-pathological conditions which may give rise to intestinal obstruction, vary in nature, in mode of action, and in acuteness and severity of effect. Some are *Congenital*, depending upon developmental abnormalities; others are *Acquired*, resulting from accident, disease, or physiological incapacity. Some act by compression of the bowel from without; some by constriction of the bowel within; and others by blocking its canal. Some come into play suddenly or almost suddenly, and without warning, and at once lead to complete occlusion, the symptoms are most acute, and in the absence of relief, fatal results speedily follow. Some coming into play with almost equal suddenness, and accompanied by almost equally severe symptoms, do not, however, so immediately lead to complete occlusion; some degree of permeability remains for a time, and the chances of relief are somewhat better. Other causes, again, seem to develop slowly, the symptoms in the earlier stages, at any rate, are not acute, the malady takes a chronic course; better opportunities for consideration and treatment are afforded; and fatal results, though they may ultimately ensue, can be longer averted.

The causes of intestinal obstruction may be enumerated as follows, in order as nearly as possible corresponding to the acuteness and urgency of the symptoms, and the imminence of danger to life to which they give rise; and the relative frequency with which they occur may be approximatively estimated by the numbers appended, representing the results of an analysis of 1,839 fatal cases recorded or observed:—

1. *Congenital malformations.*

2. *Internal strangulation* (646).

(a) By peritoneal false ligaments or bands, the result of previous inflammatory mischief, either under such bands, or by loops or knots, or in button-hole slits, or by kinking caused by traction, or by the margins of slits or rings produced by adhesions of parts or organs to one another, or to some part of the parietes (219).

(b) By the omentum or mesentery (in association with some abnormal peculiarity) by bands or in slits (65).

(c) By diverticula or diverticular appendages, as the obliterated omphalo-mesenteric vessels, or by diverticular knots (75).

(d) By the appendix vermiformis (42).

(e) By twisting or knotting (volvulus) and consequent compression of the bowel by itself, or by its mesentery (106).

(f) By the margins of peritoneal pouches (retro-peritoneal hernia, hernia through foramen of Winslow, and other forms of internal hernia) (39).

3. *Impaction of gall-stones* (51).

4. *Intussusception or invagination* (547).

5. *Constriction* (511).

(a) By cicatricial contractions of the bowels itself, resulting from injury or ulcerative disease.

(b) By peritoneal thickening and contraction, with sometimes matting together of the bowel, from strumous or other form of peritonitis (138).

(c) By new growths, innocent or malignant, in the bowel itself (373).

6. Compression.

(a) By displaced (and often diseased) viscera.

(b) By new growths, innocent or malignant, hydatids, &c., outside the bowel (66).

7. Impaction of foreign bodies or intestinal concretions (78).

8. Impaction of fecal masses: 'Physiological Incapacity'; *Ileus Paralyticus*: *Confirmed Constipation*, *habitual* or *accidental* (78).

SIGNS.—Every part of the intestinal tract is liable to be primarily affected by one or other cause of obstruction. But some parts are much more frequently than others, if not almost exclusively, affected by certain particular causes, and in regard to treatment, especially so far as operative measures for relief are concerned, it is often of very great importance to determine not only the cause, but also as nearly as possible the seat of the obstruction. Acute internal strangulation by bands most frequently affects the small intestine, by twisting the sigmoid flexure. Impaction of gall-stones, with very few exceptions, occurs in the jejunum or some part of the ileum. Compression and traction especially affect the small intestine. Intussusception most frequently involves the cæcum and colon, and next, the ileum. Constrictions due to morbid growths are most common in the large intestine, especially in the lower portion.

SYMPTOMS.—The symptoms and physical signs of intestinal obstruction are as a rule sufficiently constant and characteristic to establish the general diagnosis. But though they vary in acuteness, and in certain other respects, with the cause and seat of the obstruction, it is often very difficult, and sometimes impossible, to determine without exploration the differential diagnosis, however important it may be to do so.

The symptoms and signs commonly presented, the variations met with in different cases, and the special indications afforded by such variations may be stated as follows—the symptoms and signs especially characteristic of each form of obstruction being summarily repeated, or further discussed in subsequent sections.

1. **Pain.**—In a very large proportion of cases of obstruction depending upon most causes pain is the earliest, or one of the earliest symptoms; and in a greater or lesser degree, though it may change in character, and from time to time remit in severity, it usually persists more or less continuously and constantly very nearly to the end. The impaction of a gall-stone or foreign body, the commencement of an intussusception, or the strangulation of a portion of bowel occurring suddenly, is usually signalled by an access of acute, indescribable pain, often 'doubling the patient up,' and sometimes producing faintness, and even collapse. Strangulation by bands or in situ, after a period of incarceration, or as the result of twists, when the bowel is not suddenly gripped as it were, gives rise to pain, which, though supervening somewhat gradually, rapidly becomes almost equally severe. Strictures of the bowel, and ob-

structions due to the pressure of tumours, displaced viscera, &c., cause—at any rate in the earlier stages—comparatively little pain. Obstruction of the large intestine by impaction of feces is attended by scarcely any actual pain, the patient as a rule complaining simply of fulness, weight, and discomfort.

The pain experienced varies in its cause and character in different stages. At the onset it is, doubtless, due to the injury immediately inflicted on the serous or mucous coat of the bowel; but it is very speedily increased and maintained, and sometimes probably is started, by the effects of the congestion and distension of the compressed blood vessels on their accompanying nerves. Somewhat later comes the pain associated with distension of the bowel itself; and this is increased, at more or less frequent intervals, by paroxysmal exacerbations of acute suffering, which accompany the futile peristaltic efforts of the intestine to move on the solid, liquid, or gaseous matters accumulated above the obstruction. Such exacerbations of suffering are probably due, not only to tension of the intestinal walls generally, but in some measure also to traction upon the injured parts. At a still later stage, when inflammation is established, the pain and tenderness, localised or diffused, of enteritis and peritonitis supervene.

The pain in the early stages of acute strangulation, or of impaction of gall-stones or foreign bodies, is increased, or if it have temporarily subsided, is rekindled, by pressure on or about the spot corresponding to the seat of the lesion; and often there is little or no general tenderness. In intussusception the pain is often relieved to some extent by moderate pressure. In chronic obstruction there is but little pain and tenderness on pressure, and some degree of relief even may sometimes be afforded by gentle, supporting pressure, diffused over one portion or other of the distended abdomen.

Associated with the actual definite pain, are the general physical anxiety and distress always present to a greater or less extent, and in expression almost characteristic of intestinal obstruction or severe intestinal trouble.

2. **Vomiting.**—Vomiting is a very constant symptom of intestinal obstruction, from whatever cause. It may commence almost simultaneously with the occurrence of the obstruction, in which case it may be regarded as sympathetic, and due to shock associated with the injury inflicted. Or it may come on somewhat later; in which case it depends, in part, upon the forcing backwards into the stomach of the accumulated intestinal contents, their onward progress being arrested by the obstruction, and in part upon reflex irritation associated with injury or inflammation of the peritoneum. At whatever period it may have commenced, the vomiting recurs with greater or less severity at more or less frequent intervals until the termination of the malady, although sometimes comparatively long intermissions occur. As a general rule, the nearer the seat of obstruction is to the stomach, and the more acute the cause, the earlier does vomiting come on, the more severe is it, and the more frequently does it recur. Early, severe, and frequently repeated vomiting indicates obstruc-

tion of the small, rather than of the large intestine. When the obstruction is high up in the small intestine, but below the opening of the ductus communis choledochus, the vomit usually contains an admixture of bile, more or less altered it may be, and is but little offensive. When the obstruction is below the middle of the small intestine, the vomit is commonly 'fecaloid' in appearance and odour. When the obstruction is in the colon, or even the lowest part of the ileum, the vomit is more or less decidedly feculent in character, and sometimes contains distinct fecal masses. It appears to be clearly established that great distension of the intestine may render the ileo-cæcal valve inefficient, to such an extent as to permit regurgitation from the large into the small intestine.

The occurrence of feculent or stercoraceous vomit was formerly ascribed to reversed or antiperistaltic action of the bowel. The possibility of such reversed peristalsis has, however, been disputed and the matter may be regarded as at present undecided. Practically, it is obvious that contraction of the bowel on its contents must press them in the direction in which they can most easily go; and if they cannot pass onwards, in consequence of obstruction in front, they must pass backwards in the direction in which the way is open.

3. *Constipation*.—Constipation is of necessity a constant symptom of intestinal obstruction. It may be absolute from the first, or may become absolute after a variable period during which more or less scanty fecal evacuations may be passed. It must be borne in mind that even after complete occlusion has occurred, there may remain in the bowel below the seat of obstruction some portion of its contents, and the secretions and excretions of the mucous membrane being added, the evacuation of these by natural effort, or by aid of enemata, may give rise to the false idea that the occlusion is not complete, or that relief has been obtained. Often, however, the bowel below the obstruction at once ceases to act, and after death may be found to contain feces, although the constipation has been absolute. This is more likely to occur when the seat of the obstruction is high up. In intussusceptions, especially in the more chronic cases, the bowel is rarely altogether impermeable from the first, though later it becomes so, from the effects of inflammatory swelling. In such cases, sudden constipation is often followed by a period during which small quantities of fecal matter, mixed with blood and mucus, are passed, and this is succeeded by absolute constipation so far as fecal matters are concerned, blood and mucus only being passed. In strictures of the bowel, either simple or from morbid growths, or in compression by tumours, &c., constipation comes about comparatively slowly, and is often only rendered absolute by a twist or kink of the bowel, or by impaction of some portion of its contents. A very constricted condition of the canal, especially of the small intestine, in the absence of accidental plugging, suffices to permit the onward passage of its normal contents.

4. *Abdominal distension and swelling: Meteorism*. The occurrence of obstruction, from

whatever cause, is followed by distension of the intestine above the seat of obstruction, from accumulation of its contents. But the degree of distension, and the rapidity with which it comes on, vary with the cause and seat of the obstruction. In acute internal strangulation distension comes on rapidly and severely; in chronic obstruction it comes on gradually; in intussusception it rarely occurs, at any rate during the early stages. The portion of bowel immediately above the seat of occlusion is first affected, and sometimes its position can be recognised by the 'slight fullness to palpation,' and the 'much more definite dulness to percussion,' presented where many of the other indications of obstruction are scarcely perceptible, or even absent' (Brinton). More or less speedily the distension increases, and the whole extent of bowel above the obstruction becomes affected. The more rapidly distension takes place, and the greater its degree, the more serious as a general rule is the aspect of the case, and the sooner is a fatal result likely to ensue. In the earlier stages, when the seat of obstruction is in the duodenum or high up in the jejunum, the distension is limited to the epigastrium or upper part of the abdomen, the lower parts appearing sometimes sunken. When the obstruction is below the middle of the small intestine or in the cæcum, the distension occupies principally the middle region of the abdomen at first, but gradually extends over into the flanks, the small intestines passing into the regions of the colon. When the hepatic flexure or the first part of the transverse colon is affected, distension appears at first in the right flank. When the obstruction is in the sigmoid flexure or the rectum, more or less speedily after distinct fullness of the left flank the whole region of the colon becomes distended, and the transverse colon often becomes especially prominent, leaving the mid-region of the abdomen below comparatively sunken. But very soon, either by implication of the small intestine from accumulation of contents, or from insufficiency of the ileo-cæcal valve—or more usually, perhaps, from extension of the sigmoid flexure over the front of the abdomen, and doubling down of the transverse colon—the distension becomes general. It must be borne in mind that the colon may be so distended and displaced, as to completely cover in, and conceal from examination, the small intestines. The abdominal distension occurring during the earlier stages of obstruction is characterised by tympanites, and more or less tension of the abdominal walls, with but little tenderness on pressure—sometimes, indeed, moderate pressure affords a sense of relief. Fluctuation is rarely obvious. The distended portions of bowel, as already indicated, can often be made out, and in many cases the peristaltic efforts and movements of the small intestines can be clearly recognised from time to time, through the abdominal wall, by sight and touch. One coil of intestine can be perceived rising up and becoming prominent, and then sinking down and giving place to another; and sometimes waves of action, as it were, seem to pass along a considerable length of bowel. Such movements recur at irregular intervals, and are

accompanied by gurgling noises and sensations (borborygmi), and by exacerbation of suffering. They are most frequently met with in cases in which the obstruction is of a chronic character, and is seated in the cecum or first part of the colon. They are less commonly recognised when the obstruction is low down in the colon, the sigmoid flexure, or the rectum; and they do not as a rule occur in cases of acute internal strangulation, or in intussusception. They cease when the bowel has become paralysed by continued distension; or when peritonitis has supervened, or rupture has occurred.

Apart from such distension from accumulation of intestinal contents as has been discussed, certain localised swellings in the abdomen, which can often be recognised on examination, are liable to occur in connection with some forms of obstruction. Thus, intussusception commonly gives rise to an elongated, sausage-like swelling. Tumours of various kinds; misplaced viscera compressing the bowel; growths occupying the bowel itself, especially the rectum, and foreign bodies, intestinal concretions, and, though very rarely, gall-stones—all of these may cause swellings perceptible to the eye, or appreciable on digital examination, either of the external surface, or by the rectum or vagina.

5. *Disarrangement of the urinary excretion*—In occlusion of the intestine occurring high up, especially in cases of acute strangulation, the excretion of urine is usually diminished to a great extent, and sometimes is almost or entirely suppressed. This may be due in part to the persistent vomiting, and consequent diminution of fluid for absorption (Barlow), in part to some vicarious secretion into the bowel (Brintow), and in part to some reflex inhibitory influence, exerted through the sympathetic nervous system upon the excreting function of the kidneys (Sedgwick, Fagge). When the obstruction is low down, affecting the lower part of the colon or the rectum, there is no marked diminution in quantity; there may even be an excess of limpid urine excreted, with sometimes, however, a difficulty in voiding it.

6. *General aspect, signs, and symptoms*—In cases of acute obstruction from the first, and in the later stages of chronic obstruction, the general aspect of the patient is more or less characteristic. The countenance is expressive of physical anxiety and distress: the eyes are sunken, the nose pinched, the cheeks hollow, the lips pale or purplish, and the complexion faintly livid; the general surface is pale, cool or cold, and either dry or covered by profuse clammy perspiration; and although the mental faculties are as a rule undisturbed, there is a disposition to terror, from which the sufferer is from time to time aroused by exacerbations of pain, or recurrence of vomiting. The pulse is small and thin, and towards the end becomes thready. Usually it is increased, but sometimes (for a time at any rate) it may be diminished in rapidity. The temperature is often lowered to a very marked extent, but rises if peritonitis sets in. Sometimes there is more or less dyspnoea, due either to reflex nervous influence, or to pressure upwards of the diaphragm by the distended bowel below, and the latter cause also often

gives rise to distressing hiccough. The voice is altered in character, and towards the end is almost or entirely lost. The tongue is red; dry and pointed, or dirty brown and covered by thick tenacious mucus, coloured by coagulated material. The patient suffers from severe and constant thirst, which often he fears to assuage, lest vomiting should be provoked. In some exceptional cases death has been preceded by subdelirium and coma, and in others, still more exceptional, by violent delirium and convulsions. In children convulsions occasionally occur at the commencement or during the early stages of intussusception, as well as towards the end, and probably arise from reflex nervous disturbance. The torpor commonly noticed may depend not only on general depression, but also in great measure upon imperfect aeration of the blood, from interference with respiration, and the coma, convulsions, and other nervous symptoms which occur in rare cases, have been attributed to uræmic poisoning from suppression of urine.

7. *Collapse*.—Collapse may occur at the commencement of an acute, or may immediately precede the fatal termination of a more chronic case of intestinal obstruction. When it occurs at the commencement, as in acute strangulation, acute intussusception, or sudden impaction of a gall-stone or foreign body, it is due to the shock of the injury at the moment inflicted; when it occurs after a more or less considerable interval, whether in an acute or in a chronic case, it is usually associated with rupture of the intestine, and extravasation of its contents into the peritoneum.

DIAGNOSIS.—The general diagnosis of intestinal obstruction rests on the history of the case; and on the recognition and due appreciation of the symptoms and signs above discussed. In order to arrive at a right conclusion, not only must all the symptoms be fully considered, but careful and thorough examination of the abdomen must be made, by palpation and percussion of the external surface, and by exploration of the rectum and vagina. Such thorough examination should be instituted, and the differential as well as the general diagnosis made out as clearly as possible at the earliest practicable period, before general abdominal distension or the superposition of complications can have obscured the indications first presented. In some cases it may be desirable to administer ether or chloroform, in order to facilitate the examination by relaxing the abdominal muscles, and to save the patient from needless increase of pain. In all cases in which the symptoms indicate acute strangulation, the rings and openings of the abdominal walls must be carefully examined, and the previous or actual existence of an external hernia inquired into. In cases of chronic obstruction in which occlusion has come about gradually, or is even yet incomplete, it is especially necessary to explore the rectum as thoroughly as possible, by the introduction of the finger, or even of the whole hand. In the female, exploration *per vaginam* is often no less useful.

Various morbid conditions may give rise to symptoms—pain, vomiting, constipation—more or less closely resembling or simulating those of

intestinal obstruction. Among such may be mentioned certain forms of colic, such as hepatic colic or renal colic; ulcerative enteritis, especially of the cæcum and appendix cæci; perityphilitis; and intense peritonitis, such as follows perforation. In these conditions there is arrest of action, but not mechanical obstruction of the intestine; a distinction which it is important to bear in mind. The history and progress of the case, together with due recognition of the more distinctive concomitant signs and symptoms usually presented by each of such conditions, serve as a rule to establish the diagnosis, though it may be often difficult, and sometimes may even remain doubtful.

COURSE, COMPLICATIONS, AND TERMINATIONS.—The tendency of intestinal obstruction, from whatever cause, is towards a fatal termination, at an earlier or later period according to circumstances, and with or without the supervention of more or less obvious and extensive complications. But in respect to the more acute forms, there are scarcely any in which relief may not be afforded, sometimes coming about spontaneously as it were, almost as suddenly and unexpectedly as the lesion has occurred, sometimes resulting after an extended period of suffering, and sometimes consequent on the treatment adopted. In the more chronic forms, with the exception of those depending upon impaction of feces, and some others perhaps (as chronic intussusception), complete and permanent relief is less likely to be obtained; and death, though considerably longer delayed, is almost more certain to ensue sooner or later, in spite of temporary relief afforded by operative measures or in other ways.

The *complications and accidents* that are liable to occur and to conduce to the fatal result are:—peritonitis starting from the seat of the lesion, and more or less rapidly spreading and becoming general; enteritis; ulceration and perforation of the bowel; sloughing of the strangulated or intussuscepted portions, hæmorrhage into the peritoneum or into the bowel; pneumonia, due to the entrance of vomit into the air-passages, or to pyæmia from absorption of decomposing and poisonous material; gradual asphyxia from interference with respiration by abdominal distension; uræmia; coma; and syncope from cardiac depression and cerebral anæmia.

In cases of acute strangulation, and others in which the occlusion has been sudden and complete from the first, and in which timely relief has not been obtained, the average *duration* has been found to be from five to six days. But death may occur within a few hours, or not until after the lapse of ten days or a fortnight. In cases of constriction or compression, in which complete occlusion has come about gradually, or even has not been finally established, the duration of life varies greatly according to circumstances and the complications which arise, and it may be prolonged for weeks, months, or even years.

TREATMENT.—The treatment of intestinal obstruction must necessarily be determined by the cause and the circumstances and conditions of the particular case with which we may have to do—and therefore can be more specially indi-

cated and discussed in the subsequent consideration of the several forms of obstruction. But some general statement of methods of treatment may be not inappropriately given at once, inasmuch as tentative measures for relief are often called for before any definite conclusion as to the precise cause of the trouble can be arrived at.

1. *Purgatives.*—As a rule, when the existence of obstruction is established, and emphatically in all acute cases, violent purgatives are to be avoided. They tend to increase rather than to relieve the mischief. The object should be in the first place to soothe, and not to irritate and excite the suffering part. In cases in which it may have been deemed right to administer a strong purgative in the first instance, (and this is often done before the physician or surgeon is called in) failure of effect decidedly contraindicates the repetition of any similar dose. When all urgent symptoms have subsided, however, and in the more chronic cases, mild laxatives (especially some salines) often prove of great value—but caution in their administration is necessary.

2. *Sedatives.*—In almost all cases of intestinal obstruction sedatives and antispasmodics are demanded; and opium and belladonna, conjoined or separately, are the most useful and reliable medicines we possess. They should be given freely, but with judgment, according to the effect produced. They may be administered by the mouth, or, if the vomiting is severe and frequent, by the rectum, or by subcutaneous injection, in the form of morphia and atropine. In very acute cases the inhalation of chloroform or ether may sometimes be desirable, and may prove at any rate temporarily efficacious in relieving urgent suffering.

3. *Enemata.*—Injections more or less copious of simple gruel, soap and water, with or without the addition of oil, castor oil, turpentine, or ether, or of pure olive oil in quantity, are constantly of great service in cases of intestinal obstruction, not only in establishing the diagnosis, but also in affording relief to a more or less complete extent. In many cases it is advantageous to administer the enemata with the body inverted, or at any rate with the lower part well raised, and at the same time to manipulate the abdomen (*massage—abdominal taxis*), but this must be done with caution. When very copious enemata are deemed desirable, they may be administered more gradually, and probably more safely, by the syphon and hydraulic pressure than by means of the syringe. It has been sought to estimate the seat of the obstruction by the quantity of fluid that can be thrown into the rectum; but as a general rule no satisfactory conclusion can be thus arrived at.

4. *Insufflation.*—In cases of intussusception, insufflation of air by means of bellows has sometimes proved efficacious in affording relief; but in almost all other forms of obstruction this method of treatment has rather added to the distress of the sufferer.

5. *Local applications.*—Hot fomentations and poultices, especially with the free application of local anodynes (solutions of opium, belladonna, hemlock, or acornite), often materially relieve suffering, and thus, as well perhaps as by causing determination to the surface, and lessening in-

ternal congestion, favour recovery. On the other hand, the application of ice-bags to the surface of the abdomen has been strongly advocated, and in some cases has certainly seemed to be productive of benefit. Galvanism to the surface—or with one pole introduced into the rectum—with the view of stimulating the peristaltic action of the bowel, has also been advocated.

6 *Abdominal taxis* (Hutchinson); *massage*.—Careful manipulation of the abdomen, with movement of the body from one position to another, has in some cases proved successful in bringing about relief of intestinal obstruction.

7. *Surgical operations*.—In many cases operative measures of one kind or other are urgently demanded, and seem to afford the only chance of rescue from impending death, or from more or less prolonged suffering. And although the statistical results hitherto may not seem very encouraging, yet careful consideration of the causes of failure in the past, and due regard to recent advances in surgical treatment and appliances generally, warrant the belief that such measures will be adopted more frequently, under more favourable circumstances, and more successfully in the future. The surgical operations demanded in intestinal obstruction may be divided into those which have for their object the removal of the cause of the obstruction, and those which aim solely at affording relief by establishing an opening above the seat of obstruction. The various methods will be best discussed in connection with those forms of obstruction in which they are respectively indicated.

VARIETIES.—The several varieties of intestinal obstruction, according to the pathological cause of the condition, will now be discussed.

I. *Obstruction from Congenital Malformation*.—Arrest or modification of the normal process of development, or the occurrence of peritonitis during intra-uterine life, may give rise to congenital constriction, or to defective continuity of the intestinal canal, resulting in more or less absolute occlusion.

Constriction or occlusion of such kind is occasionally, but very rarely, met with in the duodenum at or about the entrance of the common duct, or about the junction of the duodenum with the jejunum; and in some cases has appeared to depend upon valve-like folds of mucous membrane, somewhat resembling enlarged or confluent valvulae conniventes. The lower portion of the ileum, near the ileo-cæcal valve, or about the point of junction with the omphalo-mesenteric duct, where a bend or twist takes place, appears more liable to be so affected, and instances have been from time to time recorded. The colon, and almost exclusively the sigmoid flexure, is the part of the bowel most frequently constricted by the effects of intra-uterine peritonitis and consecutive twisting; but instances are comparatively rare.

All such classes of cases are of pathological interest, rather than of practical importance. Vomiting of meconium, absence of proper evacuation, straining, convulsions, and evidences of more or less severe suffering, are followed by speedy death though in some rare instances life has been prolonged for weeks or even months. No treatment can be of avail; and surgical opera-

tion can only hasten death, or at best succeed in prolonging misery.

Very much more common, and somewhat more hopeful, are those cases in which there is congenital defect of the lower part of the rectum, or of the anus. They may be divided into—(1) Those in which there is simply imperforate anus, the bowel being closed by a membranous or more or less thick layer of tissue; and forming a distended *cul de sac* above the floor of the perineum. (2) Those in which the anus is formed and leads into a *cul de sac*, which approaches more or less closely to the *cul de sac* of the portion of rectum above. (3) Those in which the lower end of the rectum opens into the bladder, urethra, or vagina.

SYMPTOMS.—Retention of meconium, with persistent straining and sometimes vomiting, or the scanty escape of meconium by the vagina, serve to suggest the probable existence of some such defect, the more precise nature of which can generally be readily ascertained on examination or exploration.

TREATMENT.—Immediate relief may often be afforded by surgical operation, and in some instances more or less permanent good results have been obtained, and by persevering management maintained, but survival to adolescence or adult age has seldom ensued. See RECTUM, Diseases of.

II *Obstruction from Internal Strangulation*.—The various anatomico-pathological conditions which may conduce to internal strangulation have been already enumerated or indicated. Of these, some depend upon abnormalities or peculiarities for the most part developmental in origin, the existence of which—previous to exploration or post-mortem examination—cannot be predicated or ascertained; others, however, depend upon the results of previous inflammatory mischief or accidents. In every case, therefore, it is important to inquire minutely into the early history of the patient: as well as into the circumstances immediately preceding the strangulation. No better illustration of this can be quoted than that afforded by cases in which strangulation has been caused by omentum adherent to the sac of an old reducible hernia.

The *small intestines* are especially liable to become strangulated by bands or adhesions (peritoneal false ligaments), they having been found to be so affected in upwards of 90 per cent of such cases. Bands, sometimes rounded and thread- or cord-like, sometimes broader and flattened, are met with from time to time, stretching from one part of the mesentery or omentum to another, but oftener attached by one extremity to mesentery or omentum, and by the other to some portion of bowel (comparatively rarely to the large intestine), or to the abdominal wall. Very rarely indeed are they found passing from one portion of bowel to another. The bowel may become incarcerated under or behind such bands (not in front between them and the yielding anterior abdominal wall) or it may be encircled by them, and they may be looped or even knotted or twisted round it; or, again, the bowel may become so kinked by the traction of a band adherent to one point,

as to lead to its practical occlusion. The broader adhesions sometimes present slits, in which portions of bowel may be caught. Similarly, ruptures or slits may occur in the omentum or mesentery, or even in very rare instances in the suspensory ligament of the liver or broad ligament of the uterus; and these structures, especially the omentum, by adhesions may constitute broad or narrow bands, under which incarceration may take place, or by which portions of bowel may be surrounded and strangulated. Diverticula, and diverticular appendages (the obliterated omphalo-mesenteric vessels, &c.), by adhesion or by looping, and the appendix cæci, either adherent, usually by its extremity, or spirally elongated and twisted, may lead to a like result. It is worthy of note that by these, as by the foregoing conditions, the small intestine is most frequently affected. So also in the various forms of internal hernia (hernia into the foramen of Winslow, into peritoneal pouches, mesocolic, duodeno-jejunal, retro-peritoneal hernia, &c., all of which are very rare), it is still the small intestine that is most frequently involved.

Internal strangulation of the small intestine, depending on the several causes thus indicated, is most commonly met with during early adult life, the average age being about twenty-two years; and one sex does not appear to be much more liable to suffer than the other, except in the case of strangulation by diverticula, which has been observed about twice as frequently in the male as in the female subject.

The *large intestine*, as might be expected, is much more liable to become strangulated by torsion or twists than the small, and the sigmoid flexure is the part most frequently affected. Out of 106 cases, in 66 the large intestine (in 60 of these the sigmoid flexure) and in 41 the small intestine was found involved. The intestine may be twisted about its mesocolic or mesenteric axis, or one loop of intestine may be intertwined with another. In conjunction with the twisting there may be falling over, as it were, and dragging down, due to the weight of the intestinal contents. Twists of the intestine occur most frequently during the later periods of middle, or during advanced life. Their occurrence is favoured by original peculiarities in the length and disposition of the peritoneal folds, or by corresponding peculiarities acquired as the result of the stretching and relaxation which accompany the changing condition of parts at different periods of life.

The occurrence of internal strangulation is determined by the entrance of a portion of bowel into some such dangerous position as has been indicated, and its retention there. This may be due to a relaxed condition of the bowel—it may be after diarrhoea—and pressure upon it by the action of the abdominal muscles during some strain or twist of the body; to undue and irregular movement of the bowel itself; to the weight and dragging of fecal matter accumulated at one part, and the futile effort of the bowel above to move it onward; or to some accidental circumstance that can neither be ascertained nor defined. Absolute strangulation may occur suddenly and at once; or may be brought about only after an appreciable period,

by the consecutive swelling of the incarcerated or twisted bowel.

SYMPTOMS.—The symptoms of internal strangulation closely resemble those of strangulation of external hernia, but often they are more acute, and unless relief is obtained, lead more speedily to a fatal result.

Intense abdominal pain, generally in the mid-region; not infrequently accompanied by collapse, either at the very commencement or very early supervening; severe and frequent vomiting, soon becoming more or less distinctly feculent; abdominal distension, at first localised, rapidly becoming more or less general; constipation, with urgent desire and vain effort to evacuate the bowel—all coming on without warning in an apparently healthy subject, constitute a group of symptoms sufficiently characteristic. As the case progresses, these symptoms persist, increasing, or, in some respects, intermitting or decreasing in severity according to circumstances, and becoming more or less masked, modified, or added to by the symptoms of the complications already indicated as likely to arise, until either relief is obtained, or death ensues.

Cases have occurred from time to time in which all, even the most severe, symptoms of internal strangulation have been present, but in which relief has come about almost as suddenly as the distress has arisen, and it would seem that in such cases, after a period of rest, either by the aid of treatment or otherwise, the strangulated bowel has, as it were, recovered itself, and released itself from its entanglement, or reversed its twist. But such cases are rare, and very much more frequently it happens that death results, either very quickly from shock, or within four or five days from intense peritonitis, following, or without rupture of the bowel.

TREATMENT.—The treatment of a case presenting the above symptoms resolves itself into the question as to whether more palliative measures should be perseveringly adopted, and the patient allowed to take his chance; or whether an attempt should be made by surgical operation to release the bowel, and thus afford opportunity for recovery (laparotomy), or to give relief by opening the bowel above the seat of obstruction (enterotomy).

During the earliest periods, and before the nature of the case is fully pronounced, there can be no doubt but that palliative measures alone should be adopted. Such measures consist in perfect rest; relaxation of the abdominal parietes by position, the application of either ice or a hot anodyne fomentation (each having its respective merits) over the especially suffering part; and the administration (after collapse has passed) of opiates and belladonna—by the mouth, subcutaneously, or by suppository, or of chloroform or ether by inhalation, as circumstances may indicate. If the physician do not venture to advise, or the surgeon be not bold enough to adopt operative interference, similar measures may be pursued still further, inasmuch as they tend to relieve suffering, and to lengthen the time during which relief may possibly come about. Enemata may be used, but strong purgatives can only add to the distress, and increase the danger of the patient. A little ice may be

sucked with advantage from time to time; but it is worse than useless to attempt to introduce food or medicine in bulk into the stomach, only to be again speedily vomited.

Abdominal taxis.—After one, two, or at most perhaps three days (according to the circumstances and conditions of the particular case) have elapsed, without abatement, or with probable increase in the severity of the symptoms, when the nature of the case is clearly pronounced, and especially if the seat and cause of the obstruction are indicated, surgical operation appears to the writer imperative; and the earlier this is done, the better is the chance of success. The writer cannot forbear expressing in this place the strong feeling and conviction, after long consideration and some experience, that he entertains on this matter. Before proceeding, however, to the use of the knife, it may be well under chloroform to try the effect of changes in the position of the body, and of 'abdominal taxis' by gentle, firm, sustained manual compression of the part of bowel presumably strangulated and distended, and by attempts at movement in one direction or another. The good effects of sustained compression, with the view of emptying the distended bowel of its contents, rather than of pushing it back, in the reduction of external hernia, are not sufficiently generally appreciated and systematically attempted. And further, every surgeon of experience has met with cases of external hernia in which the movements or joltings of a journey to the hospital have resulted in reduction. So it may be with some cases of internal strangulation.

Abdominal section.—If such attempts fail, an incision should be made in the middle line downwards or upwards (as the indication may be) from the umbilicus into the abdomen, of sufficient extent to permit the introduction of the fingers, and the seat and cause of the obstruction sought for. As a rule, it may be better to extend the incision so far as to afford a clear view of the strangulated bowel; but it must be borne in mind that the longer the incision the more, probably, will the distended bowels protrude, and the greater will be the difficulty in replacing and retaining them. Any constricting band that may be discovered may then be divided, and the bowel released, or a twisted portion may be restored to position. The chief difficulties likely to occur arise from the protrusion of distended bowel, which is apt to hinder proceedings. Punctures may be made by a fine trocar and canula; but all such punctures should be carefully closed by ligature or suture. The chief immediate danger is that of giving way of the bowel at the seat of strangulation at the moment of release, and extravasation of its contents; but in cases in which this happens, it is almost certain that similar rupture would have speedily occurred if matters had been allowed to take their course. Any such opening in the bowel should be at once closed by suture, and every effort made to prevent extravasation into the peritoneal cavity. It has sometimes been found desirable to attach the edges of the ruptured portion to the abdominal parietes, with the view of establishing an artificial opening.

In cases in which there has been an external

hernia, it may be preferable to make the incision in the groin, and to extend it upwards as far as may be needful. In several such cases (four in the writer's own experience) the cause of strangulation has been found to be omentum adherent to the sac of the old hernia, division of which up in the abdomen has resulted in release of the strangulated bowel. After the operation the abdominal incision should be carefully closed, and the patient kept for some time thoroughly under the influence of opium.

It must be admitted that the statistics of operations for internal strangulation do not seem encouraging. In 61 out of 95 recorded or observed cases death followed more or less speedily, and in 34 only did recovery take place. But the causes of failure are obvious. In most cases there has been either some error in diagnosis, or the operation has been performed too late, and at a period when recovery under any circumstances would have been hopeless. Increased accuracy in diagnosis; earlier resort to operation; and the adoption of improved surgical methods, among which must be especially urged the use of antiseptic precautions, may be confidently expected to yield better results in the future.

Colotomy.—In cases in which it appears that the lower part of the colon or sigmoid flexure is strangulated by twisting or doubling over, and in which it is deemed inexpedient to perform abdominal section, temporary relief at any rate may be afforded by lumbar colotomy—right or left. Or simple puncture of the colon by a fine trocar and canula may give relief, temporary or permanent, by affording escape for the flatus.

Enterotomy.—The operation of enterotomy is applicable to cases of chronic, rather than of acute strangulation, and will be subsequently referred to.

III. Obstruction from Impaction of Gall-stones.—Gall-stones may enter the intestine, either after passing down the gradually dilated duct, or after a process of inflammatory adhesion and ulceration between the gall-bladder and the duodenum or colon. It is in this latter way probably that gall-stones large enough to block its canal get into the bowel, and hence in such cases, though there is usually a previous history of more or less suffering in the hypochondriac region (which may assist the diagnosis), yet those paroxysms of pain and the jaundice which accompany the passage of gall-stones down the duct have not been experienced. Having entered the intestine, gall-stones may either pass along until they escape by the anus—sometimes giving but little trouble during their passage, sometimes being temporarily arrested, or damaging the bowel at one point or other, and giving rise to pain, vomiting, deranged action of the bowels, &c.; or they may become firmly impacted, and completely obstruct the intestinal canal. Obstruction from such cause, however, is comparatively rare, occurring in only about 8 per cent. of the cases of acute obstruction. It is met with about four times as often in the female as in the male subject; and almost without exception, or with very few exceptions, after late middle life—most frequently after the age of sixty.

The gall-stones which have been found to cause obstruction have been from one to two inches or more in longest diameter. As a rule they have been single, in some instances conglomerate. In a large proportion of cases they have been impacted in the duodenum or upper part of the jejunum; in some few instances about the middle of the ileum; and, again, in somewhat more cases, in the ileum near the ileo-cæcal valve. Impaction in the large intestine very rarely occurs, and has scarcely ever led to a fatal result, but in some instances it has been attended by very severe symptoms.

Impaction is favoured by natural or accidental narrowing of the bowel, and doubtless is aided or maintained by swelling of the mucous membrane and spasmodic contraction round the stone, as well as by a more or less persistently contracted condition of the bowel beyond it.

SYMPTOMS.—The symptoms following impaction often come on suddenly, and are usually very acute; and death, preceded by all the indications of intense enteritis conjoined with those of acute obstruction, as a rule occurs in five or six days, if it have not occurred earlier as the result of shock. Recovery rarely takes place. In some few exceptional cases, however, relief has come about even after periods of severest suffering, by the release and onward passage of the stone; in some, the bowel has become stretched into a kind of diverticulum, in which the stone has remained lodged, a way by it being left; in some, after adhesion and ulceration, an opening has been formed between the small intestine and the neighbouring part of the colon through which the stone has escaped, and in some, again, after similar processes between the bowel and abdominal wall, the stone has escaped externally, or has been removed by operation.

DIAGNOSIS.—The diagnosis of obstruction by gall-stone is aided by consideration of the age, sex, and previous history of the patient; the character and acuteness of the symptoms; the localisation of the earliest pain; and sometimes by the recognition on examination of a more or less distinct hard lump, corresponding to the obstructing gall-stone.

TREATMENT.—None other than palliative measures can as a rule be recommended; but having regard to the extreme danger of the condition, and the severe suffering of the patient, the operation of enterotomy would seem to the writer to be justifiable.

IV. Intussusception or Invagination.—By intussusception or invagination is understood the passage of one portion of intestine into the immediately adjoining portion.

Intussusceptions that have given rise to no symptoms during life are not infrequently found on *post mortem* examination, especially of the bodies of children, and those who have died of brain-disease. Such intussusceptions occur *in articulo mortis*, or immediately after death; they are easily reduced, are almost equally easily reproduced or imitated and are accompanied by no sign of inflammation. They are of no practical import. But their possible occurrence should be borne in mind, lest, when met with, they should lead to false conclusions as to the cause of death or previous suffering.

ÆTIOLOGY.—Intussusceptions occurring during life, and causing intestinal obstruction, are most frequently met with during infancy or early childhood. About one fourth of the cases on record have occurred during the first year, and more than one half during the first seven years of life. The male subject appears to be more liable than the female, in the proportion of about two to one.

The occurrence of intussusception would appear to be brought about, in the first place, by some irregular or disorderly peristaltic action of one portion of bowel, conjoined with inaction or paresis of another, dependent upon some ill-defined or unascertainable cause or other of derangement. Sometimes it follows diarrhoea or violent straining; sometimes it is associated with the presence of worms, or of masses of imperfectly digested food; and sometimes with the pressure or dragging of some new growth. Having once commenced, the intussusception goes on increasing, more or less continuously, as the result of peristaltic action. The portion of bowel first invaginated, as a rule, advances at the expense of the receiving portion, which turns in to form the middle layer. The length of bowel involved varies greatly in different cases, as a matter of course. But the process may go on until the portions first involved, having traversed the whole length of the colon, may reach, or even protrude or be expelled from the anus.

ANATOMICAL CHARACTERS.—As a rule, with but very few exceptions, it is the upper portion of the bowel that passes into the lower. In ordinary cases the intussusception is *complete* and *single*, and thus a transverse section shows three rings of bowel, a longitudinal section, three layers of bowel on each side; the outer and middle layers having mucous surfaces in mutual contact, and the middle and inner having serous surfaces in mutual contact. In some rare cases, however, the intussusception is said to be *incomplete*; in such a funnel-shaped process is drawn down, usually by the dragging of a pedunculated tumour, from some part of the intestinal wall into the canal. In some cases, again also rare, the intussusception is *double*, the whole intussusception-mass being received into another portion of bowel; under such circumstances four rings or layers are shown on section.

Between the middle and inner layers the mesentery, or mesocolon, or both, as the case may be, are also received, and these determine, from the first, peculiarities in the conformation of the intussusception; and the consequent compression of their vessels, and arrest of the circulation through them, bring about complications and more or less characteristic effects, such as congestion and swelling, ecchymosis, and even considerable hæmorrhage.

Almost any part of the intestinal tract may be involved, but some parts are involved much more frequently than others. Thus in upwards of 50 per cent. of the cases, the ileum and cæcum have been found passing into the colon (*Intussusceptio ileo-cæcalis*); in about 30 per cent. the small intestine has alone been involved—the ileum in most of these (*I. ilealis*), the jejunum

in a few (*I. jejunalis*), the duodenum is still fewer (*I. duodenalis*). In some a portion of ileum invaginated in another portion has passed on through the ileo-caecal valve into the colon (*I. illeo-colica*). In about 12 per cent. of the cases the colon only has been involved (*I. colica*). The rectum, though it constantly forms the receiving layer of an extended intussusception, is very seldom primarily affected, except as the result of the dragging of, or pressure upon some new growth.

Symptoms.—The symptoms of intussusception usually appear suddenly and are very severe. First, there is pain, often most intense and agonising, sometimes like that of colic, sometimes 'straining and tearing' in character, felt most distinctly at a spot corresponding to the commencing lesion. In children convulsions sometimes occur. Vomiting speedily supervenes, and the vomited material is often streaked or mixed with blood, and, sooner or later, usually becomes feculent. Diarrhoea soon sets in, and, accompanied by severe straining and tenesmus, recurs at frequent intervals. The evacuations, at first fecal, very early are stained with blood, and soon consist of little more than blood and mucus, with only a slight admixture of fecal matter, or none at all. The occlusion of the bowel is often not complete at first, but it speedily becomes so from congestion and swelling. After a variable period, some remission in the severity of the symptoms takes place, to be again followed by paroxysmal exacerbation.

On examination of the abdomen, a firm, cylindrical, 'sausage-like' swelling, of greater or less length, can be distinctly felt, and recognised as the intussusception-mass, in almost all cases of ileo-caecal or colic invagination. In cases in which the small intestine alone is involved, such swelling is much less distinct and smaller, and often cannot be made out at all. When the intussusception has reached the lower part of the rectum, which it may do even by the second day, it can be readily felt, and its character can often be determined on examination *per anum*.

Diagnosis.—The diagnosis of intussusception of the intestine is generally established without difficulty, by the recognition of the signs and symptoms thus indicated, at any rate during childhood, and in the more acute cases. In some of the more chronic cases occurring in adult life, however, it is not always easy.

COURSE AND PROGRESS.—The course and progress of a case of intussusception may be (1) *acute*. Unless relief is obtained, the case will then terminate fatally, either speedily from shock, or within four or five days in children, or within a week or ten days in the adult from peritonitis or exhaustion. Or (2) the case may be *sub-acute*; death occurring within three or four weeks. Or (3) the case may become, or may be from the first, more or less *chronic*, and terminate in death only after a period of weeks or months, from peritonitis, or enteritis, followed or not by perforation; or from wasting and exhaustion. *Lastly*, recovery may take place after sloughing, separation, and evacuation of the invaginated bowel. The last event, which is of great interest,

and, in regard to prognosis, of great importance very rarely takes place during childhood. It follows peritonitic adhesion between the invaginated and receiving portions of bowel, and death of more or less of the former from deprivation of blood-supply. Numerous cases of this nature are on record, varying in detail. In most of them it has been some portion or other of small intestine that has come away. In some, however, the caecum with its appendix and portions of the colon have been found. Sometimes the sloughed intestine is evacuated in shreds or fragments, sometimes in its entirety. Such separation and evacuation take place, as a rule, in from eleven or twelve days to three or four weeks, and much earlier in the case of the small than of the large intestine. In some instances the adhesions have given way at or immediately after the separation of the slough, and fatal extravasation of faeces has occurred; and in some a permanent stricture has resulted after fair prospect of recovery had been afforded.

TREATMENT.—*Acute* intussusception, especially in the child or infant, demands prompt and active measures for its relief. Purgatives can only increase the mischief, palliatives are, as a rule, of little or no permanent avail, though opium and belladonna may sometimes do good by relieving pain, checking undue peristaltic action, and thus hindering the progress of the lesion, and affording a possible chance of recovery, or, at least, by rendering the remaining hours of life comparatively free from suffering.

When once the diagnosis is established, resort should be had without delay to mechanical or operative treatment, for in such measures, according to the results of experience, lie the best prospects of complete and permanent relief. First, a copious enema of oil, or oil and thin gruel, should be gently and slowly injected, the body being inverted, and moved from one position to another, abdominal taxis and manipulation being, meanwhile, carefully and systematically carried out, or, in place of liquid injection, insufflation of air by means of bellows may be employed. If the intussusception have protruded from the anus, it should, of course, be first replaced, and if felt in the rectum pushed up as high as may be practicable. Numerous cases are on record in which such means have been attended by success. But should they fail after full and fair trial—and more than three or four attempts should not be made unless signs of improvement in the condition are manifest, then surgical operation—laparotomy—becomes justifiable, and increasing experience encourages its adoption. Laparotomy should be undertaken before there has been time for the formation of adhesions, or the supervention of general peritonitis. The abdomen having been opened, with all due precaution, by median incision of requisite extent, the intussusception is usually found without difficulty, and may be traced upward and downward. Reduction may generally be effected with comparative ease by gentle traction upon the upper part of the invaginated portion, combined with gradual working up of the lower part by manipulative pressure from below upwards upon the receiving portion (Hutchinson). After the operation, the wound must be carefully

closed, an abdominal bandage applied, perfect rest secured, and after-treatment on general principles carried out.

In 15 out of 58 recorded cases this operation has resulted in recovery; in 43 it has been followed by death. Although in most of these reduction was effected. It is probable, however, that a much larger proportion of successful than of unsuccessful cases have been published, and the figures must therefore be taken for what they may be worth; they suffice, however, to justify the more frequent and earlier adoption of such means of relief, especially under the protection of antiseptic precautions.

In the more chronic forms of intussusception, and especially in the adult, resort to operation is not so urgently called for. Palliative measures, and particularly the administration of opium and belladonna, with enemata from time to time, are often of the greatest service, and, as already indicated, recovery after sloughing of the intussuscepted bowel, or portions of it, not infrequently takes place, although consecutive and dangerous complications may sooner or later arise.

V. Obstruction from Constrictions.—The anatomico-pathological conditions involving some portion or other of the intestinal wall, which may give rise to obstruction, have been already enumerated or indicated. Regarding them the following further statements may be made.

1. *Simple cicatricial stenoses* may result from the effects of injuries inflicted by caustic poisons or foreign bodies, such are most likely to be found in the upper part of the small intestine, they are, however, very rare. Similar stenoses may follow the sloughing of intussusceptions, or the ulceration produced by temporarily impacted gall-stones, faecal masses, or foreign bodies, or dysenteric, tubercular, or syphilitic ulceration of considerable extent and long standing. The dysenteric stenoses are most frequently found about the flexures of the colon, the tubercular in the lower part of the ileum or caecum, and the syphilitic in the rectum or lower part of the colon. Typhoid ulceration is very rarely followed by stenosis.

2. *Peritonitic thickening and contraction*, with more or less matting together and constriction of the bowel, most frequently involves the small intestine or the flexures of the colon.

3. *New growths of innocent character*—fibromata, myomata, lipomata, and papillomata (benign villous growths)—are from time to time met with, connected with some part or other of the intestinal wall, and causing more or less obstruction, either by themselves blocking the canal, or by leading to dragging down of the part to which they are attached. Such growths often become polypoid. They are (with the exception of myomata and lipomata) most frequently met with in the rectum, sometimes in other parts of the large intestine, very rarely in the small intestine.

4. *New growths of malignant character*—fibrous cancer, forming hard, narrow constrictions, slow to ulcerate, scirrhus, oencephaloma, colloid cancer, epithelioma, cylindroma, and sarcoma—are much more common; and from the readiness with

which they involve the whole circumference of the bowel, much more rapidly lead to serious obstruction than do those of an innocent character. In about 80 per cent of the cases such growths have been found affecting the rectum; in about 15 per cent the colon and caecum; and in only about 5 per cent some part or other of the small intestine.

SYMPTOMS.—The various conditions thus described, develop more or less gradually; and the symptoms to which they give rise are chronic in character, and in their earlier stages by no means well marked. Disordered, irregular, and imperfect action of the bowels, and general discomfort occurring from time to time, with intervals of comparative ease, constitute the earliest indications. Later, and after a very variable period, as the constriction increases, the trouble becomes greater and more constant, and the symptoms of obstruction become more pronounced. In most cases abdominal distension (meteorism)—localised or general, and accompanied by sensations of fulness, foetid eructations, shortness of breath, and pains in the back, varying in degree from time to time—comes on sooner or later; and except when the seat of obstruction is in the rectum, the peristaltic movements of the intestines at intervals become very manifest through the abdominal wall. The pain experienced is very variable in character and severity, and is often paroxysmal, with periods of complete intermission. As the case progresses towards a fatal termination, the distress becomes extreme. Absolute occlusion, as a rule, comes about slowly. In some cases it is never completely established; but in other cases it occurs suddenly, from impaction of hardened faeces or undigested food, or from other cause, and in such the symptoms at once correspondingly increase in severity. It is worthy of note that even in cases in which the seat of constriction is in the sigmoid flexure or rectum, the greatest faecal accumulation and corresponding discomfort are observed in the caecum.

DIAGNOSIS.—The general diagnosis of obstruction from constriction, as a rule, is not difficult, but the differential diagnosis as to the precise nature of the constriction is often very obscure, except in those cases (the large majority) in which a stricture, or the presence of some new-growth, can be discovered on examination per anum. The previous history often supplies important indications, and should therefore be thoroughly investigated.

COURSE AND TERMINATIONS.—The course of all such cases, though very variable in duration, is progressively unfavourable, and sooner or later death supervenes, usually from peritonitis with or without perforation, or from exhaustion from prolonged suffering.

TREATMENT.—The treatment must be determined and varied in accordance with the symptoms and indications presented from time to time. In the earlier stages, soothing and palliative measures should be adopted during periods of exacerbation of suffering; and during periods of comparative relief laxatives may often be given with great advantage. In all cases in which there is reason to suspect the existence of some cause of constriction, the most careful attention to diet,

and the administration from time to time of such medicines as favour a soft, semi-solid condition of the faeces, should be insisted upon.

Operation.—In the later stages resort must be had to surgical operation, and the greatest relief may often be afforded, and life prolonged, by the establishment of an artificial anus by opening the bowel above the seat of constriction, either by incision through the peritoneum—enterotomy; or by post-peritoneal incision—lumbar colotomy, right or left. Laparotomy is altogether out of the question.

In cases in which there is reason to believe that the constriction affects the *small intestines*, enterotomy should be adopted. An oblique incision in the right iliac region, more or less parallel with and above Poupart's ligament, having been made and cautiously carried down through the various structures, the peritoneum is to be opened to a limited extent, and the first protruding portion of distended small intestine is to be seized, and being well pulled out, opened by very limited incision. In the case of the small intestine, it is needless, on account of the semi-fluid nature of the contents, to make a large opening, and it is obviously disadvantageous to do so. The margins of the opening in the intestine are then to be sutured to the margins of the external wound. This operation, especially advocated by Nélaton, has proved successful in affording relief and prolonging life in a considerable number of cases (10 out of 16). One great drawback to it, in the event of prolongation of life, lies in the extreme inconvenience and annoyance the patient suffers from the continual escape of liquid faeces in the part of the body operated upon—an escape which there is the greatest practical difficulty in restraining.

In cases in which the seat of constriction is in the colon or rectum, lumbar colotomy (post-peritoneal enterotomy) is to be performed, on the right or left side according to the indications afforded. The merits of this operation in relieving suffering and prolonging life in such cases, can scarcely be esteemed too highly.

After the establishment of an artificial anus, and the rest from constant irritation thereby afforded, the constricted bowel may recover to a certain extent its permeability.

VI. Obstruction from Compression from without.—Various viscera, enlarged and displaced as the result of disease—especially the uterus and ovaries, and in rare instances the spleen, the pancreas, and even the kidney; tubercular or cancerous glands; tumours of the omentum or other parts of the peritoneum; tumours growing from one part or other of the abdominal or pelvic parietes, or from the contained viscera; hydatid cysts, &c., may so compress a neighbouring portion of bowel as to lead to obstruction, which either may be brought about gradually, or from some accidental cause may be suddenly determined.

SYMPTOMS.—The symptoms more or less closely resemble those of obstruction, chronic or acute, arising from other causes.

DIAGNOSIS.—Careful examination of the abdomen, including thorough examination *per vaginam* and *per anum* (sometimes the introduction of the whole hand into the rectum is especially

likely to be useful), together with the history of the case, and the consideration of the collateral signs and symptoms, will generally suffice to establish, approximatively at any rate, the diagnosis of obstruction of the bowel from external compression.

TREATMENT.—The treatment of this condition consists, first, in the removal of the cause, if practicable; secondly, if this should be impracticable, in relieving the obstruction. By altering the position of the body, the displaced viscera may sometimes be so moved as to cease to compress the bowel, tumours, uterine and ovaries especially, may be taken away by operation, hydatid cysts may be tapped; and thus relief may be afforded. Or again, by manipulation or by the effects of copious enemata, the bowel itself may be so moved as to be no longer compressed, or after a period of rest, under the influence of sedatives, it may release itself. But if none of these measures should be applicable or successful, and if the symptoms of obstruction be severe, resort to one or other of the operations (laparotomy, enterotomy, or colotomy) already discussed, may become needful. In some cases, of this class especially, relief has been afforded, and the bowel has recovered itself, after puncture by fine trocar and cannula and aspiration. The ultimate prospects must depend upon how far the compressing cause can be removed.

VII. Obstruction from Impaction of Foreign Bodies, Intestinal Concretions (Enteroliths) &c.

a. Foreign bodies in bulk, such as bones, coins, buttons, knives, forks, pins, needles, &c., accidentally or intentionally swallowed, occasionally find their way on from the stomach into the intestines. In a considerable proportion of cases they pass on, and are evacuated *per anum* without very much inconvenience; in some cases they give rise to enteritis and various other intestinal troubles; in some rare cases they lead to more or less complete occlusion, with acute or sub-acute symptoms.

SYMPTOMS.—The symptoms of impaction of foreign bodies in the bowels vary with the extent of injury inflicted, and the degree of obstruction occasioned.

DIAGNOSIS.—The diagnosis of such cases rests on the history, and on the recognition of the presence of the foreign body on palpation of the abdomen, or examination *per rectum*.

TREATMENT.—The treatment of this condition must be determined by the general circumstances and urgency of the case. As a rule, purgatives can only do mischief. Soothing remedies give temporary relief, and favour the gradual onward passage and ultimate expulsion of the foreign body. If absolute impaction has clearly taken place, and the symptoms are urgent, enterotomy and extraction may be justifiable, or even imperative. The wound in the intestine may either be carefully closed by suture, and the bowel returned; or its edges may be attached to those of the external wound, and an artificial anus temporarily established. In some instances, such procedures have been encouraged and favoured by the previous formation of inflammatory adhesions between the bowel and the parietes.

A. Foreign bodies—as hair, &c., indigestible constituents of the food—as the skins, seeds, and stones of fruit (the husks of cereals, and oats especially), orange-pulp, and the curd of milk in young children; and some medicinal substances—as magnesia, chalk, oxide of iron, &c., swallowed bit by bit from time to time, may accumulate in some part or other of the bowel. Becoming matted or felted together, and agglutinated by the intestinal mucus and other secretions, these bodies may form rounded masses, which sooner or later may give rise to more or less complete obstruction. Such masses constitute the large proportion of the so-called 'intestinal concretions' in the human subject.

c. In some rare instances, however, hard stony concretions (*enteroliths*), consisting for the most part of phosphates of lime and magnesia with organic material, and resembling those not infrequently found in some of the lower animals, have been met with. These usually have as a nucleus some foreign body, or portion of hardened altered feces.

Intestinal concretions are almost invariably found either in the cæcum or in the rectum. Their presence may commonly be recognised on examination. They are, as a rule, slowly formed, and only give rise to complete occlusion after a considerable period, during which repeated attacks of more or less persistent abdominal discomfort and distress have occurred. Death may be brought about by gradual exhaustion, or by the effects of inflammation with or without perforation; or recovery may follow the evacuation of the concretion, either *per vias naturales*, or through an ulcerated or artificial opening.

Foreign bodies introduced into the rectum, or which have passed down and there become impacted, and concretions similarly situated, may be removed *per anum*.

VIII. Obstruction from Impaction of Fæces.—Habitual or accidentally prolonged constipation may lead to definitive obstruction by impaction of fecal masses, conjoined with paralysis and inaction of the bowel from distension, and contraction of the empty portion below. Sometimes the occlusion is rendered more absolute and irremediable by the doubling or dragging down of the bowel by the weight of its contents. The seat of the obstructing fecal mass is usually the sigmoid flexure or the rectum, but corresponding accumulation is at the same time often found in the cæcum. This cause of obstruction is most frequently met with in advanced life, and especially among lunatics or idiots.

SYMPTOMS.—The symptoms of fecal impaction are characterised by their chronicity, and complete occlusion as a rule comes about slowly. There is little or no actual pain during the early stages, and even during the later stages, in the absence of complications, it rarely becomes acute. Vomiting is altogether absent at first, or slight and rare; towards the end, however, there may be fecal vomiting. Abdominal distension only comes about gradually. Absolute constipation is only slowly established, and sometimes is preceded by more or less frequent scanty diarrhoea-like evacuations. The fecal mass can sometimes be felt on abdominal examination, and much more often on rectal exploration, which in

such cases should always be thoroughly carried out.

DIAGNOSIS.—The diagnosis of such cases is determined generally without difficulty by the history; by the absence of acute symptoms; by the process of exclusion of other causes of obstruction; and by the aid afforded by physical examination.

COURSE.—In a considerable proportion of cases of this kind relief may be afforded by appropriate treatment. In some cases, however, death ensues from gradual exhaustion; in others from chronic peritonitis, and in others from ulceration of the bowel, followed or not by perforation and acute peritonitis.

TREATMENT.—In this form of obstruction of the bowels, very copious enemata, administered through a long, soft tube, carefully introduced and insinuated onwards as far as practicable, are especially useful. Such enemata—consisting of thin gruel, soap and water, oil, with or without turpentine, to the extent of two or three pints or more, should be given and repeated at intervals as indicated. Or a stream of warm water from a vessel raised to a height, through a long tube, may be advantageously made to play upon and wash away, portion by portion, the fecal mass (iii). Sometimes the mass may be cleared out of the rectum by the finger or a spoon. In some cases galvanism to the abdominal wall, in some the application of an ice-bag, in others hot fomentations or immersion in the hot bath may be useful.

In the earlier stages, laxatives or even purgatives, as calomel in a full dose, or castor oil, may often be given with safety and advantage. A teaspoonful of Rochelle salts in a cupful of mutton broth is an old but often efficacious remedy. In the later stages, and when purgatives have been found to fail or to increase distress, opiates are indicated; and belladonna in large doses seems often to exert a peculiar and beneficial influence.

When relief has been obtained, the greatest care as to diet and after-management is necessary, in order to prevent that recurrence of trouble to which the patient remains liable. See CONSTIPATION. ARTHUR E. DURHAM.

INTESTINAL WORMS.—This combined term was formerly much employed in medical literature, as an equivalent for the simpler expression *entozoa*, which latter title is far better, more comprehensive, and now in general use. To be sure, nearly all the internal parasites of man, at some time or other during the course of their development, play the part of *intestinal* worms, within either the human or animal host; but since this particular residence frequently constitutes neither the only locality they occupy, nor the principal feature of their life-record, it is well that the use of those possibly misleading words should be discontinued. See ENTEROZOA; PARASITES. WORMS, and VERMES.

T. S. CONNOLD.

INTESTINES, Diseases of.—GENERAL REMARKS.—Morbid affections of the intestinal tract are of very frequent occurrence at all ages; some being limited to certain periods of life, others presenting no such restriction.

The direct exposure that the canal offers to external influences, in the form of ingesta, will account for the causes of a large proportion of cases. So many irritants to disease have thus the opportunity to exert their immediate influence, and produce what may be termed *primary* affections of the canal. On the other hand, since much of the normal physiological work of the tract depends for its performance on a healthy condition of other functions, especially of the blood-circulation and nervous system, any disturbances of these processes will tend to influence injuriously intestinal digestion, and thus give rise to *secondary* diseases of the bowel. And it is evident that an improper preparation of the food in the intestine must in its turn affect the nutrition of the tissues generally, and among others those of the canal itself. In no case is the interdependence of the functions on one another seen more completely than in affections of the digestive apparatus.

For this same reason it is that the symptoms essentially due to any disease of the intestines may be considerably masked by more prominent signs of mischief elsewhere, though secondary to the intestinal affection; whilst in other cases the disease we may be called upon to treat is out an expression on the part of the bowels of a morbid state, primarily connected with some other organ.

Besides the direct nutritive disturbance of all organs and tissues of the body that must obviously follow any morbid condition of the intestinal function, there is a most close sympathy between the processes of digestion and the nervous system, or, in other words, a dyspepsia which may be so slight as practically to produce no apparent alteration in the general state of the body, may yet distinctly affect the mental condition, and all degrees of disturbance, from a mere irritability of temper to a complete hypochondriasis, may result. The frequent association of headache with dyspeptic symptoms is a further illustration of the connection; in reference to which we cannot avoid noticing the very extensive nervous supply that is provided by the sympathetic system to the chylipoietic viscera.

Although structurally continuous with the stomach, and closely associated with it in its working, the intestine nevertheless is exceedingly prone to be diseased independently of that organ, while at other times both suffer together. Certain spots in the course of the tract favour the development of certain diseased states, and it is rare to find the entire length of the canal involved; whilst one portion of the tube, the jejunum, is probably less liable to disease than any other organ of the body.

The indications of intestinal disease are frequently extremely vague and uncertain. The subjective symptoms, such as pain, may be completely wanting in some of the most serious conditions, or out of all proportion to the severity of the case. An ulcer may proceed to perforation, and a fatal result happen, with but a minimum of discomfort, whilst an attack of simple colic may be agonising. Nor is physical examination so fruitful in its results in the case of intestinal disease as it is in the affections of many other organs, though perhaps in no other

region is the *tactus cruditus* so valuable. Many of the states to be considered below undoubtedly pass through their whole course without giving the slightest indication of their existence that can be recognised by physical examination. An investigation of the evacuations at present furnishes information within the narrowest limits. From all these circumstances, a diagnosis of many diseases of the intestines is almost a matter of pure inference and conjecture, based upon a careful consideration of all circumstances, with due regard to the value of experience.

In respect to treatment, very much may be done with the means at our command. The removal of causes is in a large proportion of cases easy, and a complete cure may be effected. And whilst some of the remaining cases admit of little or nothing being done for them, a greater number can be partially relieved by palliative remedies.

The several diseased conditions of the intestines may now be discussed, for the sake of convenience, in alphabetical order.

1. **Intestines, Abscess in Walls of.**—In the course of severe cases of enteritis—phlegmonous—where the inflammatory process affects all the coats of the bowel, and the products infiltrate the different tissues, collections of pyoid cells may be met with, but with no well-defined limit, which may be regarded as abscesses. Such bodies may burst into the intestine, leaving small ulcers; or through the peritoneal coat, and so conceivably cause perforation.

In the chronic enteritis so often met with in scrofulous subjects, the solitary and agminated glands may undergo slow suppuration, and form abscesses which end by bursting into the lumen of the gut.

Such morbid products are rather of *post-mortem* interest, since they give rise to no symptoms during life which will permit of their formation being diagnosed, apart from the general existing enteritis, and are practically incapable of treatment.

2. **Intestines, Albuminoid disease of.**—The intestines appear to be affected with albuminoid disease next in frequency to the spleen, liver, kidneys, and lymphatic glands, and it is rare for the alimentary canal to show signs of this degeneration until it has become far advanced in the above-named organs. It is stated that the intestines are affected in 42 per cent. of all cases (Halershon).

ANATOMICAL CHARACTERS.—As in other organs, the inner coat of the arteries, particularly of those surrounding the solitary and agminated glands, appears to be the starting point of the albuminoid change, from which it gradually extends to adjacent tissues, until the whole thickness of the bowel may be replaced by this material. In milder cases it is limited to the mucous and submucous coats, which in all cases are the first to suffer. Considering the exceeding proneness of the Malpighian corpuscles of the spleen to undergo this change, it is noticeable that the solitary and agminated glands of the intestine, which are of similar structure, should long resist

the degeneration, and in many cases may be quite unaffected. Sooner or later, however, the albuminoid granules appear in these structures, until the whole gland is involved. The mesenteric-lymphatic glands are usually implicated; and in severe cases the mesenteric and peritoneal vessels, and even the appendices epiploicae (Hayem).

The naked-eye appearance of the mucous membrane is that of a pale, thickened, leathery layer, often of a 'peculiar glistening aspect' (Friedreich). The pallor is very striking. When the degenerative process has become extreme, the surface is ulcerated, especially over the follicles, from fatty degeneration and breaking down of the new material, the diminished blood-supply by the constricted vessels leading to this result.

The small intestine, and particularly the lower part of the ileum, is the favourite seat of the disease, which sometimes extends upwards to the duodenum and stomach, the colon is sometimes affected.

Symptoms.—The most prominent symptoms which this condition gives rise to, so far as the alimentary canal is concerned, are diarrhoea and hæmorrhage. Since the other important viscera are always simultaneously affected, other symptoms coexist.

The diarrhoea is rather characterised by fluidity than undue frequency of the stools, though the latter does occur, the evacuations are often greenish from altered blood. It is rare to find either pain or tenderness; and the diarrhoea when once established rarely ceases.

Dr. Grainger Stewart has shown that hæmorrhage from the surface of the mucous membrane, independently of any ulceration, is of frequent occurrence, and he considers it as due to rupture of the diseased vessels.

Treatment.—Enemata of starch and opium are the most efficacious, though their effect is at best but temporary. The writer, however, has seen a case, where extreme degeneration of all the abdominal viscera was present, almost completely recover on removal of the cause, namely, a suppurating joint.

3. Intestines, Atrophy of.—A general atrophy of the intestines accompanies a wasting of the entire body from any serious cause of malnutrition, such as starvation, where the organs are estimated in fatal cases to lose 42 per cent. of their weight, becoming extremely thin and transparent.

Intestinal catarrh, particularly in children, may lead to atrophy of the bowels, even to an extreme degree.

Wasting of parts of the canal are of more frequent occurrence from disease. This is well seen in cases where an artificial anus has been made, the gut below the opening becoming thin and shrivelled. In all cases where any considerable stricture of the intestine exists, the portion beyond the obstruction atrophies more or less. This subject will be found fully discussed by Nothnagel, in the *Zeitschrift f. Klin. Medicin*, IV., 1882, p. 422.

4. Intestines, Catarrh of.—This is a mild form of intestinal inflammation in which, how-

ever, the essentials of that morbid process are present, though in a slight degree (see *Intestines, Inflammation of*).

5. Intestines, Contraction of.—The calibre of the intestinal canal may be diminished by the pressure of tumours; by structural changes in the walls; or by displacements of portions of the bowels in invagination, &c. Such causes of stricture are more properly described under intestinal obstructions. See *INTestinal Obstruction*.

The term contraction may be applied to that state of shrinking which the gut is liable to present below the seat of any permanent stricture, whatever its nature, just as the portion of the canal above the obstruction tends to dilate. It is a condition that calls for no interference, being of no practical importance.

A spurious contraction of part of the intestines may be occasionally seen *post mortem*, due to extreme spasm of the muscular coat. Congenital malformations, producing contraction of the canal, may be met with.

6. Intestines, Dilatation of.—The normal diameter of the small intestine may be taken as $1\frac{1}{4}$ inch throughout, and that of the large intestine as gradually diminishing from $2\frac{1}{2}$ inches at the cæcum to $1\frac{1}{4}$ inches at the upper part of the rectum. But the canal is evidently capable of distension much beyond these limits, as may be recognised when large accumulations of flatus exist. Such conditions, however, may disappear after death the bowel returning to its proper capacity. These dilatations, therefore, may be regarded as temporary, and it is impossible to say what may be the extreme limit reached and recovered from.

Other forms of distension of a more permanent nature are frequently observed.

Cases have been placed on record by Peacock, Crisp, and others (see *Path. Soc. Trans.*) where extreme distension occurred without any obvious cause, but associated with marked constipation. In one case the colon was uniformly distended to a diameter of six to eight inches; and in another the average diameter of the small intestine was twice the normal. In this case the stomach shared in the distension; and the person had been a large eater, and extremely fat.

In the greater number of cases the dilatation is attributable to the existence of some stricture in the course of the canal. It is rare for any distension to follow an acute obstruction, though it is not absolutely unknown; but a chronic stricture is almost invariably associated with more or less dilatation of the tube immediately above. The length to which this may extend is largely dependent on the duration of the case; and inasmuch as a persistent obstruction is usually located somewhere in the large intestine, it is the colon that is most frequently distended, and this may be so excessive as practically to obliterate the ileo-cæcal valve. The mere accumulation of the contents above the obstruction is doubtless one factor in causing the distension; but a diminished resisting power on the part of the gut probably co-exists, brought about by malnutrition of its textures. The muscular coat of the dilated portions is usually hypertrophied,

while the mucous membrane is thinned and peculiarly liable to ulceration, the decomposing contents furnishing an exciting cause for this result.

The existence of any extreme dilatation may be recognised by inspection or manipulation of the abdomen, especially if the parietes be thin and wasted, as they frequently are in such cases. Fæcal vomiting may of course occur in connection with the existence of a dilated intestine, but this is rather to be attributed to the primary obstructing cause, in the symptoms of which the few indications peculiar to this condition are merged.

Paralysis of the muscular coats, by diminishing the resistance of the bowel allows of its distension. This is well exemplified in the extreme dilatation from flatus which so frequently accompanies acute peritonitis.

7. Intestines Gangrene of.

ÆTIOLOGY.—The immediate cause of the complete death of a portion of the intestine is the complete arrest of the flow of blood through the part affected. This obstruction may be produced by:—

(i.) Embolus of the superior mesenteric artery. Several cases of this condition have been recorded, the emboli originating from the heart.

(ii.) Thrombus of the mesenteric veins. The perfect stasis induced by this cause is of very rare occurrence, but it has been seen to follow invasion of the portal vein by malignant disease.

(iii.) Local constrictions of the bowel. This is by far the commonest cause of gangrene, and is the probable sequence of an invagination or ileus. In these states the vessels are pressed upon by the altered position of the gut, which, with the continuously increasing pressure of the œdema that follows the venous obstruction, leads to complete stasis.

(iv.) The more gradual obstruction to the blood-flow, from constriction of the vessels by diseases of their walls, leads to sloughing, which frequently tends to occur in albuminoid disease of the intestines.

(v.) Sloughing also occurs as a sequence of the inflammatory state, when the process is of such intensity that complete cessation of the circulation takes place in localised spots, usually affecting the mucous membrane only, though occasionally penetrating deeper, ulcers remaining after separation of the sloughs.

ANATOMICAL CHARACTER.—From the nature of the constructive tissues of the intestine, the gangrene which is met with is of the moist variety. The portion of bowel which is affected is at first of an intense red colour, gradually increasing, and becoming purple, even to black. The extreme congestion of the vessels leads to effusion of blood into the tissues, which, however, are uniformly coloured; decomposition rapidly takes place in the stagnant blood, and the products acted on by the sulphuretted hydrogen of the intestines become black, all traces of red colour being soon lost. Meanwhile the mucous membrane and muscular coats are swollen and softened by the serum and blood with which they are infiltrated, and a dark-black or ash-

grey, soft, pulpy mass is finally thrown off from the healthy tissue.

The extent of substance which may undergo this necrosis and be separated is extremely variable, from a mere slough of half an inch in diameter or smaller, to portions of bowel several feet in length. Dr Pencock records a case where 12 feet were passed in eight portions during a period of three years.

SYMPTOMS.—The occurrence of symptoms whereby mortification of the bowels can be diagnosed is not to be expected. The signs resolve themselves into those of the existing inflammatory state. It is not until the sphæclus has been passed, or that signs of ulceration are manifest, that the existence of gangrene can be ascertained. A very few hours suffice to produce this condition when once the cause is established, and it cannot be either arrested or cured, the separation of the slough is to be desired, though fatal hæmorrhage may be associated with this process. The circumstances of this state preclude any treatment being specially directed towards it.

8 Intestines, Hæmorrhage from.—An escape of blood from the intestines is a sign of certain morbid conditions rather than an actual disease itself, hence the cause of the hæmorrhage must be sought for.

ÆTIOLOGY.—The causes of intestinal hæmorrhage may be thus indicated:—

a. *Increased blood-pressure.*

Intense hyperæmia or extreme congestion.

B. *Affections of the intestinal walls.*

1. Injuries of the bowels.

2. Ulceration.

3. Vascular growths, hæmorrhoids.

4. Amyloid disease of the walls.

γ. *Primarily altered blood-states—*

1. Purpura hæmorrhagica.

2. Leucocythæmia.

3. Yellow fever and severe intermittent fever.

δ. *Occasional causes—*

Rupture of aneurism into intestine.

Vicious menstruation

The mere enumeration of the causes must here suffice. It is obvious that the relative frequency of these conditions differs considerably, and in many cases the cause is at once apparent, whilst occasionally the source of the blood may be more obscure. It would seem from statistics that intestinal hæmorrhage is of more frequent occurrence in males, as gastric hæmorrhage is more common in women, the latter fact being explained by the greater liability of females to ulcer of the stomach, as the former appears to be by the preponderance of males suffering from the determining causes of hæmorrhage, and not that the sex *per se* predisposes to such a result.

SYMPTOMS.—Associated with the symptoms special to the loss of blood, and which are in the main similar to bleeding from any other organ, there are the signs and symptoms of the causal disease. The extent of the hæmorrhage will necessarily largely determine the symptoms, many bleedings being so trivial as to give rise to no appreciable effects, and in extreme cases the loss being so great and sudden as to lead to rapid

collapse and death. Between these extremes all degrees of anæmia, faintness, pallor, giddiness, and failing pulse may be observed. A sensation as of a warm fluid flowing into the abdomen is occasionally complained of, but otherwise hæmorrhage in this situation is possessed of no characteristic feature. The occurrence of the above-mentioned indications in the course of a disease liable to lead to this condition, would point to hæmorrhage, especially if there be a fall in temperature from a previous pyrexial state.

Occasionally the escape of blood is beneficial. This is particularly the case where the cause is a congestion of the intestinal tract with or without hæmorrhoids. Thereby the fulness of the bowels is relieved, and a more equal circulation is established. In some cases of typhoid fever, contrary to what might be supposed, improvement has been noticed to follow a moderate loss of blood. (Trousseau.)

Except in such cases as when the effusion of blood is so excessive that death takes place before any escapes from the bowel, intestinal hæmorrhage reveals itself sooner or later in the character of the evacuations. Unless the cause be such as an ulceration immediately within the anus, or that the blood be sufficient in amount to escape alteration, when the bright red colour is retained, the fluid is always altered in appearance. The hæmatin is readily affected by the sulphuretted hydrogen in the canal, and converted into a blackened material, sulphide of iron being formed, which stains the feces; or a black tarry substance is evacuated, being the altered clotted blood (*see MELÆNA*). As a rule, when the blood has undergone this change, the source of it is in the small intestine; blood from the colon—where it is usually due to ulceration—being passed adherent to the feces. The height of the source, and the duration of its stay in the canal, largely determine the extent of alteration in the effusion.

DIAGNOSIS.—The history of the case; the condition of the patient; and the character of the voided blood, are the points upon which a diagnosis of the cause of intestinal hæmorrhage is to be based.

PROGNOSIS.—The amount of blood evacuated is not a sure guide to forming an opinion of the result. It is difficult to estimate the actual quantity lost, since much may be retained in the bowel. The general condition of the patient, especially the state of the pulse, is of far more importance; whilst allowance must be made for the nature of the cause, not forgetting the occasional favourable import of a flux.

TREATMENT.—In a certain number of cases bleeding from the bowel is quite uncontrollable; in others it is capable of cure, whilst in a third group it is rather to be encouraged. When arrest of the hæmorrhage is desired, rest, both general and local, is essential; the patient should be kept in the recumbent position, as thereby the liability to syncope is averted; and the canal is to be kept quiet by abstinence from food, and the use of opium, to prevent peristalsis.

The active treatment is to be directed to withdrawing the blood as much as possible from the affected region, by means of heat, sinapisms, dry-cupping, &c., to other parts of the body; and to the application of styptics to the bleeding surfaces,

or the administration of such remedies as arrest bleeding after their absorption into the blood. Among the agents which, administered by the mouth or rectum, act locally, may be mentioned turpentine in 30 to 60 minim doses, with two or three ounces of starch as an enema. Injections of equal parts of tincture of perchloride of iron and water may be given; or acetate of lead in combination with opium. Tannic acid and the vegetable astringents are usually too slow in their effects to be of much avail. Probably the most effective remedy is ergotin, administered subcutaneously in 2 grain doses dissolved in glycerine, and repeated if necessary. This acts not only by constricting the vessels, but by diminishing the blood-pressure. Bitartrate of potash in doses of two drachms, and the local application of a saturated solution of perchloride of iron in glycerine, are of great benefit in arresting the bleeding of piles; for which purpose also, as well as for vicarious hæmorrhage from the lower bowel, the writer has found frequently repeated doses (m. r. to viii.) of tincture of hamamelis of much advantage.

When the hæmorrhage is distinctly the result of engorged vessels, its occurrence should not be checked, provided it be not excessive. Sulphate of magnesia in full doses, with a few minims of dilute sulphuric acid, is then of great service; by determining an effusion of the watery part of the blood, the congestion is relieved and the hæmorrhage is arrested, the patient meanwhile refraining as far as possible from taking fluids.

The giving of stimulants is a procedure that involves careful judgment. Whilst undoubtedly the tendency of loss of blood is to produce death by syncope, it is also true that faintness itself favours the cessation of the bleeding, and, so far as a general direction can be given, stimulants should be avoided, unless there be reason to fear, from the condition of the patient, character of the pulse, &c., that the syncope is excessive. Short of that, alcohol, by temporarily increasing the heart's power, increases the bleeding.

Transfusion of blood, when practicable, should be resorted to in extreme cases.

9 **Intestines, Hyperæmia and Congestion of.**—The former term is here applied to those conditions of vascular engorgement where the excess of blood is, primarily at least, on the arterial side of the capillaries (active congestion, fluxion, determination of blood), whilst the latter term is restricted to cases where the fulness is caused by some obstruction to the venous flow (passive congestion). Doubtless either of these conditions may lead to the establishment of the other, but it is desirable to consider them separately, not so much for the difference in the causes producing them, as for the great difference in their results.

It should be remembered that even within the limits of health a considerable variation is met with in the degree of vascularity of the alimentary canal. The fluctuating periods of rest and activity undergone by the tube are associated of necessity with alternations of comparative hyperæmia and anæmia, as during the digestion of a meal or during fasting. It is impossible, therefore, to draw any line beyond which the vascu-

lar fulness can be said to be abnormal; as it is equally impossible to say exactly where hyperæmia and normal gland-change end, and catarrh begins.

ANATOMICAL CHARACTERS.—The appearances seen *post mortem* are far from being always indicative of what existed during life. For an extreme arterial fulness may completely disappear after death, from contraction of the vessels; whilst venous engorgement more or less completely remains.

ETIOLOGY.—The causes of intestinal hyperæmia are as follows:—(a) Mechanical and chemical irritants, foreign bodies, and poisonous drugs. Spices and highly seasoned food, and alcohol, any substance, in fact, which may be swallowed, and at all exceeds the blandest nature, may bring about an abnormal degree of hyperæmia of the whole or part of the canal. These causes act locally and directly upon the vessels.

(β) Vaso-motor paralysis of the splanchnic area. If from any cause the normal tone of the mesenteric vessels is diminished, by inhibition or removal of the tonic influence excited by the sympathetic, the vessels dilate and hyperæmia ensues. It is in this way that diarrhoea following certain emotional states is to be explained. The intimate relation which has been shown experimentally to exist between the splanchnic nerves and the vaso motor system generally, but especially with the cardiac innervation by means of the 'depressor nerve,' whereby any considerable peripheral resistance in the systemic capillary area which impedes the action of the heart is compensated for by a dilatation of the mesenteric vessels, renders it probable that an undue hyperæmia of the intestines is of very frequent occurrence.

(γ) Collateral hyperæmia, or the fulness of the vessels of one region caused by contraction of the vessels of another, as in the shrinking of the cutaneous vessels from cold, extensive burns, &c. In such cases the blood, remaining constant in amount, must distend other vessels; and those of the abdominal viscera, including the intestines, are peculiarly liable to become engorged, as explained by what may be called their compensating paralysis.

The causes of passive congestion are the following:—(a) A general congestion of the entire intestinal tract will be produced by any of those causes which lead to universal congestion of the tissues, as dilatation of the right heart from lung-disease. Pressure by tumours or other conditions on the inferior vena cava above the liver, or on the portal vein, will bring about the same result. So also will any obstruction to the portal circulation in the liver. This is by far the commonest cause of intestinal congestion, since cirrhosis of the liver, whenever produced, directly tends to it.

(β) A congestion of a portion of the tube occurs when any obstruction exists to the venous flow of that part, as is marked in cases of invagination and strangulation of the bowel. The rarer conditions of embolism of branches of the mesenteric arteries, or thrombosis of the veins, will induce intense congestion. This state also forms a part of the vascular changes undergone by any inflamed part.

SYMPTOMS AND EFFECTS.—These conditions may of themselves give no evidence of their existence. But the following results may ensue.—

From hyperæmia, an increased secretion of mucus and other intestinal fluids, often more watery than normal, which with an increased peristalsis, induced by the same irritant that led to hyperæmia, produces a diarrhoea. Provided this over-functional activity be limited to the production of the normal secretions of the part, and increased healthy action only, the condition of hyperæmia is not exceeded, but the passage into catarrh is easy, and persistently sustained arterial fulness will sooner or later pass into that state.

The increased blood-pressure may be sufficient to induce diapedesis of the red corpuscles, or rupture of the capillaries, leading to capillary hæmorrhage, submucous petechiæ, &c.

As regards congestion, the more complete the obstruction to the flow, the greater will be the pressure in the veins, whose thin walls favour the transudation of the serous part of the blood, and so produce an œdema of the mucous membrane and entire thickness of the bowel, with a transudation on both surfaces, into the canal itself and into the peritoneal cavity, the latter being more marked. The fluid effusion in this case is dependant entirely on mechanical conditions, whilst the flow in hyperæmia is mainly the result of increased secreting activity. Hæmorrhage from rupture of the smaller vessels is of frequent occurrence, and may be very considerable.

A prolonged state of congestion—and as a rule the cause is such as to determine a permanent state—leads to certain structural alterations in the tissues of the bowel, from the imperfect nutrition that a chronic venous fulness permits of. The nature of the change is chiefly the infiltration of the mucous and submucous coats with an imperfectly formed connective tissue, which causes a thickening and toughness of the bowels, almost identical with the results of chronic inflammation.

TREATMENT.—It is seldom that these conditions are such as call for treatment. The hyperæmia is usually of a transient nature; and the cause of congestion is generally irremovable. Aperients, such as jalap, gamboge, &c., are sometimes beneficial, by inducing watery evacuations and so relieving the vessels, but they demand constant repetition.

The treatment of hæmorrhage has been considered, but this and diarrhoea, when due to congestion, are, unless excessive, often beneficial, and are not to be checked.

10. Intestines, Hypertrophy of.—This is always of local occurrence, a general hypertrophy, involving the entire length of the bowel, being practically unknown.

In chronic enteritis the mucous, submucous, and even muscular coats are apt to become much thickened, and though this is partly due to an excessive formation of connective tissue, there is also some actual hyperplasia of the normal textures.

In portions of the intestines above an obstruction, a true hypertrophy of the gut, particularly of the muscular layers, is to be found, and, as

already said, this is usually associated with dilatation of the tube.

It is rare for this condition to be other than inferred during life, it gives rise to no symptoms and calls for no treatment, and when established is rather of the nature of a compensatory lesion.

11. Intestines, Inflammation of.—SYNON.: Enteritis; Fr. *Entérite*; Ger. *Darmentzündung*.

Under this term are included all those structural changes in the mucous membrane of the intestinal tract which primarily follow the application of an abnormal irritant, provided that the irritant be not of sufficient intensity to produce absolute destruction of tissue. Such changes will involve more or less all the tissue-elements of the mucous membrane, and may extend to the muscular, or even the peritoneal coat. They are essentially characterised by productive, coincident with destructive features, the former leading to the formation of new material, as pus or connective tissue, the latter to ulceration or gangrene. The inflammatory process may present considerable variety in type. The simplest form, to which the term 'catarrh' may be applied, passes, by almost insensible gradations, from the tissue-changes met with in the course of normal digestion, to a distinct condition of disease. Or it may be that, superadded to the above-named characters of inflammation, are certain specific characters due either to the nature of the cause, or to the predisposition of the tissue affected, or to both, which determine the conditions known as diphtheritic, phlegmonous, dysenteric, &c.

There are thus differences in the severity with which enteritis may occur, both as regards the extent of departure from normal structure, and in respect to the symptoms which arise. But in all cases the essential characters of inflammation are present, which may be regarded as the results of the irritant, plus the efforts at repair on the part of the affected tissue.

The morbid process may affect the intestine throughout its entire length either in common with or independently of the stomach—*general enteritis*, or it may be distinctly limited to certain parts of the canal—*local enteritis*, including duodenitis, ileitis, typhitis, colitis, proctitis. As a rule the term enteritis is restricted to inflammation of the small intestine.

In respect to duration and intensity, enteritis may be *acute* or *chronic*.

(A) *Acute Enteritis*.—Acute enteritis is sometimes called *gastric remittent*, or *infantile remittent fever*—terms it is advisable to discard entirely, since they are frequently applied to very different diseases. Acute enteritis is meant to include all those cases where the essential features of an inflammation are present, varying in severity from a simple catarrh or mucos-enteritis, to those severer forms possessed of special features, such as phlegmonous or diphtheritic. The more severe cases, especially in children, are sometimes called simple *c.* English cholera, or *cholera infantum*.

Ætiology.—It is doubtful whether an idiopathic enteritis is ever met with; some cause is generally to be found.

Predisposing causes.—(a) The exposed situation of the intestinal tract to irritating sub-

stances swallowed, causes this disease to be one of frequent occurrence.

(B) The structure of the intestinal mucous membrane, with its delicate and susceptible epithelial cells, and slightly protected blood-capillaries, favours the occurrence of those changes which constitute inflammation.

(γ) Age especially predisposes to enteritis. For although it may occur at any period of life, infants and children during the period of dentition are peculiarly susceptible. A moderate intestinal catarrh may almost be regarded as a normal accompaniment of dentition, like to the increased activity of the salivary and other glands at that period. From the moderate it may easily pass into the serious or even fatal degree.

(δ) The season of the year appears to exercise an influence, for during the summer this disease is certainly much more frequent; and particularly so when there is extreme difference between day and night temperatures, or when the heat is associated with much moisture.

(e) Occasionally this malady would appear to be epidemic.

Erecting causes.—These, whatever their nature, would appear to act by inducing a hyperæmia of the tissues, which thence pass into a state of inflammation.

1. Irritating ingesta of the most varied kind, such as abnormal, ill-cooked, or improperly digested food, and irritant drugs or poisons, often cause enteritis. Of these, improper food is by far the most common, especially during the first year of life. Cow's milk alone may be at that time sufficient to produce it, and it is rare for infants to escape an attack. An excessive flow of bile into the intestine is an occasional cause.

2. Exposure to cold may be followed by inflammation of the intestines, as it may be by inflammation of the lungs, kidneys, or pleura; the factor which determines the particular organ involved is unknown. There would seem to be some other factor than the mere determination to the viscera of an excess of cooled blood from the contracted cutaneous capillaries, which probably affects the nutrition of the tissue-elements and the nervous system.

The occurrence of inflammation and ulceration of the duodenum which follows extensive superficial burns, cannot be altogether explained by the hyperæmia of the intestines, which is said to follow the superficial injury.

3. Wounds, new-growths, and the mechanical results of intussusception, hernia, impaction of feces, gall-stones, parasites, and other conditions, will lead to enteritis.

4. Inflammation of neighbouring parts may involve the intestines by extension, as from the stomach, peritoneum, or bile-ducts.

5. The specific poison of diphtheria not infrequently leads to enteritis of a characteristic nature. An inflammatory state of the intestinal mucous membrane is said to accompany or follow the exanthemata, and more especially scarlet fever; and it sometimes complicates septicæmia, particularly when this is of postseptic origin. In such cases the disease would seem to be set up, at least sometimes, by extension from the uterus along the peritoneum.

ANATOMICAL CHARACTERS.—It probably never

occurs that the whole length of intestine is the seat of inflammation, and it is not often that even the entire small intestine is so affected. It is far more frequent to find certain tracts, of a few inches or a few feet, involved. Speaking generally, the colon, cæcum, rectum, duodenum, ileum, and jejunum are affected, as regards frequency, in that order. In some situations special features are present, but the essential characters of inflammation always exist, whatever be the site.

Owing to the physical properties of the intestinal tissues, the appearances seen after death by no means necessarily correspond to what actually exists during life. Thus, the hyperæmic state of the mucous membrane, with the increased redness, varying from a more intense pink than normal up to a deep dark red, may leave but a trace *post mortem*, the vessels having become considerably emptied from the constriction of the vessels in *rigor mortis*. An increased vascularity, however, is one of the important features of the state under consideration, and it may sometimes be so intense as to lead to capillary rupture and formation of petechiæ in the mucous membrane. The tissue-elements of the gut, as a result of the irritant causing the inflammation, and with the accompaniment of an increased vascular supply, undergo changes in their appearance and behaviour. Thus the epithelial cells are in a state of cloudy swelling and increased activity in multiplication, each successive progeny approaching nearer and nearer to the embryonic type, the connective-tissue elements are similarly affected, and leucocytes transude into the tissues from the vessels. These new-formed cells constitute pus-corpuses, which are thrown off from the surface of the mucous membrane, and crowd to a variable depth the tissues of the different coats. If the primary irritant to the inflammation be of a specific character, such as the poison of diphtheria, or of an extremely severe nature, such as an intussusception or hernia, then the new-formed cells become entangled in a fibrinous coagulable exudation from the blood, and form patches of membrane more or less adherent to the surface of the bowel, depending on the depth of tissue involved. In all cases there is some œdema of the intestinal walls from serous effusion, and the free surface of the membrane is covered with a glairy mucus, containing pus-cells, and frequently crystals of triple phosphates.

The epithelium of the follicles of Lieberkuhn becomes extremely granular, and proliferates extensively, with the frequent result of blocking up the lumen of the gland, which thus becomes very prominent. The solitary and agminated glands are invariably much swollen, and very often the process of inflammation is most intense in their vicinity. Occasionally the mesenteric glands are similarly affected.

How this inflammation may terminate very much depends on the course; it may subside, and the bowel gradually assume its normal characters with no impairment of function; it may lapse into a chronic state; or it may pass on into ulceration, or even sloughing and gangrene.

To these various degrees of the inflammatory state different terms have been applied in no

very definite way. Thus, when the mucous membrane alone is affected, a *catarrh* or *mucosenteritis* is said to exist; whilst the *ulcerifer* form, affecting all the coats, and attended with suppuration, such as occurs in the neighbourhood of an intussusception, is known as *phlegmona*. When a membranous exudation is found in association with diphtheria, we have a true *diphtheritic enteritis*; and the expression *pellucida* may be more fitly applied to those cases where a similar membrane is formed, though not in connection with the diphtheria poison. Such a state is of not infrequent occurrence on the prominent edges of the valvulæ conniventes, and still oftener of the sacculi of the colon, due to the presence of hardened feces or impacted calculi. Both these latter forms are invariably associated with ulceration. The term *dysenteria* is very indifferently applied to more than one form of enteritis or colitis; the writer thinks it better limited to that form of inflammation due to the specific poison of dysentery, although the morbid appearances of such cases are almost or quite identical with some of the varieties enumerated above, the differences in the cases being dependent on their clinical history.

An enteritis associated with aphthæ is of common occurrence in children.

SYMPTOMS.—That a considerable variation is met with in the kind and severity of the symptoms presented in cases of enteritis, is only to be expected when the great difference in degree and extent of morbid change that is met with is remembered. Whilst the pathological changes that take place in a limited part of the canal are identical with those that may be found in another, to a very large extent the symptoms that arise in the two cases may be widely different. For whereas one patient may suffer from an attack of intestinal catarrh with but a trifling array of symptoms, another may succumb within a few days. There is no one symptom or even group of symptoms that is absolutely characteristic of the disease, even the general condition of the patient is not constant. In the milder forms of intestinal catarrh there may be slight pyrexia, with thirst and quickened pulse, but these symptoms may be scarcely noticeable, while, on the other hand, in the severe phlegmonous enteritis they are extreme, and the patient is in a state of considerable prostration.

The following symptoms, more or less marked, occur in different cases.

Stools.—Diarrhœa is in some respects the most constant symptom, though, when the affection is limited to the higher part of the canal, and space is given for the reabsorption of the excessive exudation, it may not only be wanting, but there may be actual constipation. The lower down the gut is inflamed, the greater the liability to diarrhœa, which hence becomes a marked character of colitis and proctitis. In the severe forms of the affection a more or less complete constipation may be due to the paralysis of the inflamed bowel arresting the peristalsis, and allowing of the accumulation of the intestinal contents above the lesion; this is obviously more complete when the enteritis is associated with any state producing mechanical obstruction, such as intussusception, or ileus.

The character of the evacuations is very variable. As a rule they are semi-fluid when diarrhoea exists; or they may consist chiefly of a liquid with a few feculent flakes; but, when time has permitted a partial re-absorption of the fluid part, the stools become more consistent, and in cases of enteritis which are chiefly due to faecal accumulation, solid, hard masses are passed.

Mucus, in greater or less quantity, is constantly present—being especially abundant in affections of the large intestine and rectum, when it is often discharged as complete tubular casts of the bowel.

Blood is not usual except in proctitis, or unless there be ulceration or hemorrhoids, and pus is seldom noticed unless the rectum be inflamed.

Owing to the imperfect performance of digestion or absorption, the motions are liable to contain many abnormal constituents—as fat, when the duodenum and upper part of the jejunum are involved, or even masses of food scarcely changed; and the altered character of the intestinal contents, with the products of decomposition, are in themselves important features in maintaining a diarrhoea. As a rule, the discharges are paler than normal, or may be even colourless; the greenish tint so often seen in the enteritis of children is due to altered bile or blood-pigment. The odour is usually extremely offensive or even putrid; though sometimes, when the evacuations are very liquid and colourless, smell may be altogether absent.

Owing to a large production of gases, discharges of flatus are of very frequent occurrence.

Vomiting, except in the severe forms, is not a common symptom of enteritis, unless the stomach be involved. In phlegmonous enteritis, however, vomiting may be persistent, and even stercoraceous; and it is relatively more frequent in children than in adults. Short of actual vomiting, nausea is frequently complained of.

Pain and tenderness.—Pain in itself is a most uncertain symptom, perhaps being scarcely noticeable in the milder forms of catarrh, whilst in colitis, the colicky, griping pains, which may or may not be relieved by pressure, are characteristic. Still more is this the case when the rectum is affected, when the straining and tenesmus constitute one of the most distressing symptoms of the malady. When the peritoneum is involved, the pain and tenderness are marked and characteristic. Both may be generally diffused over the abdomen, or may be local in character, as over the cæcum; in a large number of cases the pain is referred to the umbilical region.

General symptoms.—Among the more general symptoms, or those associated with inflammation of special regions, are the phenomena of the febrile state in a more or less marked degree. The temperature may reach 104° F., or even higher, or in some cases it may be scarcely elevated. The appetite may be unaffected, especially if the upper part of the tract be free from the disease; whilst there may be complete anorexia when the reverse is the case. Thirst is of usual occurrence, and it becomes very marked when the evacuations are abundant and fluid. The tongue indicates rather the general state of the patient, and is a less reliable index of the actual state of the intestinal

mucous membrane, than in corresponding affections of the stomach. It may be red, irritable, and glazed; or coated with a thick fur, with the edges and papillæ bright and prominent; in milder cases it can often scarcely be said to be affected.

The character of the pulse varies with the general state. Provided that the pyrexia be extreme, there is the usual dry skin and concentrated urine, with a tendency towards the production of the typhoid state, which usually is reached in fatal cases. In many cases the prostration is excessive, though the mind is usually unaffected to the end, and in a large number of cases there is a very marked irritability of temper. Notwithstanding the intimate sympathy between the alimentary tract and the brain, headache is of rare occurrence in enteritis. A persistent hiccough, presumably of nervous origin, is met with sometimes. In children the disease readily leads to a condition of collapse. The child lies in a languid, almost torpid, state; with the skin of the abdomen intensely hot and dry; whilst the extremities are cold and blue, the face is pinched, and the body generally appears shrunken. Frequently this state is interrupted by attacks of convulsions, especially if dentition be in progress. The child, too, is usually extremely fretful, and maintains an almost constant, short, feeble cry, evidently accompanied with pain.

When the disease affects the duodenum, jaundice, due to closure of the bile-duct, very often occurs. The intimate nervous relation between the rectum and base of the bladder explains the frequency of micturition, so commonly associated with proctitis.

DIAGNOSIS.—The variability and oftentimes vagueness of the symptoms frequently admits of a diagnosis of enteritis being made only by a process of exclusion. The history of improper feeding, whether temporary or prolonged, often indicates the nature of the disease; though it cannot be denied that all rules of a rational dietary are frequently violated, both by children and adults, with apparent impunity.

Diarrhoea alone can by no means be taken to indicate the existence of intestinal inflammation, it being due to many causes which leave the intestines unaffected; and the same may be said of constipation, pain, vomiting, and other symptoms. It is rather to a group of symptoms, with the previous history, that the observer must look. The character of the stools, as already described, often indicates the region of gut affected; and the existence of extreme tenderness and pain, with a hard, quick pulse, and the abdominal decubitus together, point to the involvement of the peritoneum, which an exacerbation of temperature tends to confirm. The distinctive features of typhilitis, colitis, and proctitis have been already described sufficiently to form material for diagnosis in most cases. To distinguish between inflammation of the jejunum and ileum is usually impossible, nor, practically, is it a matter of importance. The history of the case, the course of the temperature, and the characteristic rash and headache, should serve to separate acute enteritis from typhoid fever, for which it is sometimes mistaken.

PROGNOSIS.—This will clearly depend on the degree of severity of the affection, no less than on its seat and extent. Rest, which is of prime necessity to an inflamed organ, is almost incompatible with maintaining the due nutrition of the patient, and this fact renders the prognosis very uncertain.

A simple intestinal catarrh occurring in a healthy subject certainly tends, after a few days, to complete cure; but occurring, as it frequently does, in persons in ill-health, it is far more liable to pass into an obstinate chronic condition. In children, the opinion should be very guarded, for whilst in a large number of cases perfect recovery follows removal of cause and suitable treatment, others, for no very apparent reason, will, in spite of everything, progress to a fatal termination; and this is, of course, more likely to be the case where a strumous or tubercular diathesis exists. Enteritis in different degrees of severity constitutes one of the most, if not the most, important cause of infantile mortality.

In the severer forms, as they affect adults, opinion must be guided by the nature of the cause, and the general state of the patient. Recognising that the unfavourable tendencies of the patient are towards extreme prostration, to perforation with fatal collapse, or to chronic ulceration—according as those conditions are threatened, so may the prognosis be fairly made. The duration of extreme cases rarely extends beyond a few days, when, if death do not occur, the symptoms abate, and recovery, with oftentimes a tedious convalescence, follows, or a chronic condition of disease is established.

TREATMENT.—Although great variety exists in the degree of severity of the symptoms of acute enteritis, and a corresponding difference obtains in the treatment to be pursued, yet certain general principles may be first laid down, and the more special details adapted to certain conditions afterwards indicated. Inasmuch as the disease is one of a febrile nature, where, among other things, the tissue-waste is out of proportion to the repair, and at the same time the organs concerned with the preparation of the food are those mainly at fault, every effort should be made to minimise the bodily waste. This is best attained by keeping the patient in bed, which also offers the additional advantage of providing a uniform warmth.

As regards diet, in the greater number of cases of acute intestinal inflammation, the appetite is much impaired, even to complete anorexia. Providing the person attacked have been previously in good health, no harm is done by complete abstinence from food for twenty-four or even forty-eight hours. This gives a much better chance of rest to the intestine, and a better opportunity for the removal of any irritant ingesta which may have been the cause of the inflammation. The thirst during this period may be relieved by ice-cold water, with or without a little lemon-juice. It must not be forgotten that, with the mucous membrane and its glands inflamed, the conditions of normal digestion and absorption are materially interfered with, and articles of diet that ordinarily are most nutritious and easily digested, may and do become, under these altered conditions, positively harmful. The aim in

feeding the patient should be to give those materials which are most quickly absorbed, and leave the smallest amount of indigestible residue. Provided that the stomach be implicated—and it is rare that it is not so, either directly or indirectly—meat foods are badly borne; instead of the proteid constituents being digested in the stomach, they remain there and undergo putrefactive decomposition, and thus add fresh irritants to the canal lower down. If, however, as is largely shown by the state of the tongue, the stomach be tolerably free, then meat essences, made thin and allowed to stand till cold, may be given. The nausea or vomiting which is usually present is more easily overcome by giving the nourishment cold, and a few drops of lemon-juice are of great service if added to the beef-tea. Milk is very uncertain in the way it is tolerated by such patients. Occasionally it is impossible to give it, the vomiting or diarrhoea being increased by it, but equal parts of milk and soda-water may constitute sufficient nourishment to last for several days in extreme cases, and may be well borne. Lime-water may be substituted for the soda-water, but, as a rule, effervescing fluids are more grateful. The milk should be as free as possible from cream, for fats in all forms are to be avoided, since the products of their decomposition are extremely irritating. A similar objection, though not to such an extent, may be made to farinaceous foods, for the lactic and butyric acids to which they give rise in the process of pancreatic digestion will further increase any existing inflammation. If given at all, it should be only in small quantities at a time, a remark which equally applies to all other food. Nutrient enemata may be of much use in some cases.

A very great deal may be done for the patient with drugs, both in the relief of symptoms, and in aiding the cure.

It is seldom advisable to check the diarrhoea in acute enteritis, and an aperient to begin with, except evidence exist of there being any peritonitis, or that the cæcum be impacted with feces, is a rational treatment. Thereby the irritant, whatever it may be, is removed, and a better chance for recovery is given. Improper food is so commonly the cause, that the majority of cases are benefited by a preliminary purgation. This it may be necessary to repeat, especially if irritating results follow the nourishment that is given. Probably the best aperient in this case is colomet, in doses of two to four grains, given as powder. This undoubtedly cleans out the upper part of the small intestine, and it will be necessary to follow it up after a few hours with a quickly acting aperient of a saline character, or, better still, senna, if the latter can be borne. If the inflammation be confined to the colon, where, as already said, accumulations of feces are the common cause, copious simple enemata, repeated every six or eight hours, are of great advantage; and this plan may be pursued in conjunction with the aperient given by the mouth. The object has been to clear out the alimentary canal, and provided that this has been done, abstinence from food for twelve hours, and some bismuth in an effervescing form, are frequently sufficient in milder cases to put the attack on the road to cure. The water places great reliance on bismuth,

of her in the form of solution with an effervescing citrate of potash, and three or four minims of dilute hydrocyanic acid; or granular effervescing lime-juice and bismuth. The nausea or vomiting are best relieved by this treatment. Pain is of course a pressing symptom. Besides external applications of poultices or poppy-head fomentations, the internal administration of opium is very effective—five or ten drops of the tincture every four hours: the opium in these cases does not seem to interfere with the action of the aperients. Should there be peritonitis the opium must be increased in amount, to the end of giving complete rest to the gut. Several leeches applied to the anus, with the view of relieving the hyperemia of the intestinal tract, are occasionally necessary in extreme cases. When the attack is distinctly attributable to cold, a profuse sweating induced by hot baths, and ten grains of Dover's powder, is often of great benefit. In those cases where, from the duration, character of stools, and previous treatment, there is reason to believe that the irritating causes are got rid of, the diarrhoea may then require special treatment, especially when the patient has been in ill-health, or is constitutionally debilitated, in which cases an ulceration of the bowel is more likely to follow. In such cases a powder, consisting of Dover's powder, 5 grains, and carbonate of bismuth, 10 grains, given every six hours, is very efficacious. Sulphate of copper, nitrate of silver, and vegetable astringents, are frequently used for the same purpose.

So soon as the more acute symptoms have subsided, the bismuth may be still continued and gradually given with a vegetable bitter, such as calumba. But ten to fifteen minims of the dilute hydrochloric acid in an ounce of water is almost an essential to the recovery of the digestive power of the stomach.

In consequence of the great liability to a second attack which this disease engenders, avoidance of well-known harmful articles of diet, and the use of warm clothing or flannel belts, are demanded as a prophylaxis.

In infants and young children the great liability to collapse, often rapidly fatal, must be borne in mind. Stimulants in some form are almost a necessity. The following prescription is usually used by the writer:—*Liquoris Bismuthi* $\mathfrak{m}\text{ij}$ - \mathfrak{ij} , *Spiritus Ammonie Aromatici* $\mathfrak{m}\text{ij}$ - \mathfrak{v} , *Tinctura Cardamomi Composita* $\mathfrak{m}\text{ij}$ - \mathfrak{v} , *Aque* $\mathfrak{z}\mathfrak{j}$ - $\mathfrak{z}\mathfrak{j}$ according to age. Brandy in small quantities is often the means of saving life in these cases. When the collapse is not threatening, two or three drops of solution of corrosive sublimate, with syrup, 3ss. and water, 3iss., every two or three hours, is of great service. It is a more convenient mode of giving mercury than in the form of grey powder. But in one form or another the writer believes mercury to be of prime necessity. Corrections of diet on the lines indicated above are of course essential. Hot baths and other means to keep the child warm must be followed.

In the severer cases, which are lapsing into the typhoid state, the general principles for that condition must be followed; but, except in such a state, alcoholic stimulants are rarely called for.

(B) Chronic Enteritis.

Ætiology.—1. A certain proportion of the acute cases lapse into chronic when the original cause persists; or when the structural changes resulting from an acute attack are permanent.

2. Those conditions which lead to a chronic state of congestion of the intestinal tract will thereby so affect the constitution of the tissues, with a consequent disturbance of function, as to constitute a chronic inflammation. The most important of these conditions is obstruction, either at the right side of the heart, or affecting the portal circulation in the liver.

3. Chronic enteritis is the occasional accompaniment of some general chronic disease, such as Bright's disease, when the altered nature of the arterioles, and circulation of a deteriorated blood, may readily be regarded as leading to a chronic inflammation.

4. Residence in tropical climates is a not infrequent cause of inflammatory disease of the bowels.

ANATOMICAL CHARACTERS.—The intestinal mucous membrane, when it has been the seat of inflammation for any prolonged time, is thickened, tough, and of a grey or almost black colour, from a deposition of pigment, due to the chronic congestion. The epithelial cells are cloudy and ill-defined, and there is an infiltration of the mucous and submucous layers with new round-celled tissue, passing into the stage of connective tissue; hence the thickness and toughness. The lymphoid follicles are prominent and hard, and the intestinal glands are frequently blocked with cells and secretion, and form minute solid, though perceptible masses. The surface of the membrane will be more or less covered with a viscid glairy mucus, containing pus and imperfectly-formed epithelial cells, not unfrequently such mucus may be voided in the form of complete casts of the tube, and this is particularly the case in the pellicular form of colitis. Sometimes the muscular coat is thickened from connective-tissue formation. As a rule, therefore, the bowel is increased in thickness; but in children it not unfrequently happens that a chronic enteritis is associated with an atrophy of all the coats and the contained glands. It is unusual for a chronic inflammation of the intestine to exist in adults without coincident ulceration; but in children the disease may proceed to a fatal termination, and show no such condition after death.

SYMPTOMS.—Whilst many cases with a persistent cause may be said to be chronic from their outset, it is not always easy to say exactly when an acute case has lapsed into a chronic state, very much the same symptoms being continued. In such affections of the small intestine, the diarrhoea may be wholly wanting, and the bowels may be very confined. This is due to the diminished peristalsis, from orlema of the muscular coat and impaired irritability. When, however, ulceration is extreme, and especially if it be the colon or rectum that is mainly affected, chronic diarrhoea is an invariable symptom. The remarks made on the character of the stools in acute enteritis are equally applicable to the chronic state, with the addition, that solid and liquid evacuations frequently alternate. Lasting

as the disease does often for many months or even years, a general impairment of nutrition results; the function concerned in the elaboration of the food, as well as that by which the digested products are absorbed, are necessarily perverted, from the structural alteration of the organs concerned in their performance; and as a result the entire body suffers. The marasmus is speedily noticed in infants and children, whose growing tissues the less readily withstand malnutrition. Apart from the general ill-health produced, there would seem to be a special inclination for the mental qualities to become affected, so that the intellect may become dulled and sluggish, the temper irritable, and the patient may fall into a condition of marked hypochondriasis; this is particularly liable to be the case when the colon is the seat of the disease. The emaciated appearance; the dirty, muddy complexion; complicated often with a short, dry cough, dependent on reflex causes from the stomach, frequently lead a superficial observer to suspect the existence of phthisis.

DIAGNOSIS.—The grounds on which a diagnosis can be made are sufficiently obvious from a consideration of the foregoing remarks.

PROGNOSIS.—Chronic enteritis almost invariably tends towards a fatal termination, though this may be long delayed. As already said, it is, at least in adults, the colon that is chiefly the seat of this malady, and where it is almost always associated with ulceration, obstinately resisting all treatment, which at best is only palliative; the general nutrition is more and more deranged; and death from inanition finally terminates an existence of prolonged suffering and discomfort.

TREATMENT.—Owing to the unfavourable tendency of this disease, the treatment can be rarely more than palliative. The debilitating and wearying character of the malady emphatically calls for good feeding. The diet should be abundant, no less than nutritious. When the disease affects the large intestine, the ordinary digestive changes in the food have taken place, and the contents of the canal reach the colon in the normal semi-fluid condition; in this state they may be passed; but owing to the impaired movements of the affected bowel the feces are apt to accumulate, and constipation results. This should be guarded against by simple enemata, and the soothing effect of injection of warm water only is often very marked. In those cases where the enteritis is a sequence of a congestion of the intestine, the treatment must be directed to relieve if possible the cause of that congestion. Since this is usually some such intractable condition as Bright's disease, cardiac dilatation, or cirrhosis of the liver, it is not very much that can be done.

Tonics—such as quinine, iron, bark, with sea air—are of undoubted benefit; and, so far as possible, causes of mental worry should be removed.

12. Intestines, Malformations of.—These may be (a) *congenital*; or (b) *acquired*.

(a) *Congenital.*—Though seldom of much clinical importance, congenital malformations of the intestines are often of great interest from a developmental point of view. The malformation

may be of the nature of an excessive development. Thus certain parts of the canal—duodenum, colon, and appendix vermiformis—have very rarely been found double. The commonest of all these malformations are certain diverticula of the ileum, which may be found protruding from the free margin of the ileum anywhere within ten inches above the ileo-cæcal valve. The cæcal-extremities of such processes may be connected with the umbilicus by thin fibrous cords, showing them to be unobliterated portions of the vitelline duct. They vary in length from half an inch to six inches, or even more; their structure is exactly that of the ileum; and they have been found the seat of typhoid ulceration, or of perforation from the irritation of foreign bodies that have become lodged in them. The vermiform appendix may vary from half to twice the natural size.

Deficiencies of development may affect the whole alimentary canal, or only certain parts. Andral records a case where only a straight tube joined the rectum and œsophagus. The ileum may open upon an ectopic bladder. The lower extremity of the canal is frequently imperfect. Thus the rectum may end in a cloaca common to the urino-genital organs, or the bowel may terminate in a closed extremity anywhere between the brim of the pelvis and immediately beneath the skin, the anal pouch, which develops from without inwards, is in the latter case absolutely wanting, and all degrees between this and a pouch that has just failed to establish a junction with the rectum may be met with, producing the lesion known as *imperforate anus*. The valvule conniventes are sometimes wanting, or very imperfect, over varying areas of the small intestine. Congenital constrictions of different parts of the canal are occasionally met with—in the duodenum, either close to the opening of the common bile-duct or at the junction with the jejunum, in the lower end of the ileum, where some abnormality in the closure of the vitelline duct appears to be the cause, or in the sigmoid flexure. Such constrictions may be multiple, of very short extent, the canal being much dilated above, and extremely narrowed and shrunken below. The ileo-cæcal orifice has been seen contracted to the diameter of a small cedar pencil. The cause of these lesions is very obscure, but at present they are ascribed to a prænatal peritonitis or enteritis, though they may be occasionally accounted for by the existence of prominent valve-like folds of the mucous membrane.

Hernial protrusions of the mucous membrane through the other coats, often very numerous, and varying in size from a pin to a walnut, have been seen in the colon, sometimes extending into the appendices epiploicæ. They are very liable to become developed in cases of long-standing constipation.

(b) *Acquired.*—The acquired malformations include the dilatations and contractions that are associated with stenosis, and the adhesions and abnormal communications established by ulceration and peritonitis, which have been already referred to.

When any symptoms are produced by malformation of the intestines they are usually those of obstruction, and the only condition that may be amenable to treatment is *imperforate anus*.

13. Intestines. Malignant Disease of.—The new growths which are met with in connection with the intestine may, for the present purpose, most conveniently be divided into *malignant* and *non-malignant*—a clinical distinction irrespective of their minute structure. We will here discuss the former class, in which there are included those neoplasms which tend to produce a fatal result, as a rule, rapidly; and that are accompanied with a marked general perversion of nutrition.

Ætiology.—Malignant growths of the intestine, as in other situations, whilst not wholly unknown in the earlier periods of life, are rarely met with before the age of forty.

From an examination of 2,000 fatal cases of cancer, the relative frequency of intestinal cancer to that of other organs was found to be as 1 to 25 (Tanchou).

Cancer of the intestine is nearly always primary, and very frequently runs its course without any secondary formations elsewhere. Occasionally the bowels are affected by extension from neighbouring parts, and this is especially liable to be the case in the rectum, when the uterus or vagina are the seat of the disease, and in the duodenum, which may become involved in an extension from the pancreas, liver, or stomach. Primary cancer of the duodenum is very uncommon. Very rarely small nodules are found in the solitary and aggregated glands secondary to carcinoma existing elsewhere.

ANATOMICAL CHARACTERS.—Malignant disease may occur at any spot throughout the entire length of both small and large intestine, but is infinitely more often to be met with at certain special parts, notably the rectum, sigmoid flexure, cæcum, colon generally, and duodenum; the jejunum and ileum being rarely affected. There is undoubtedly a predilection for those spots where any delay may occur in the passage of the intestinal contents, such as the flexures of the large intestine; and this favours the idea that mechanical irritation is largely concerned in the causation of malignant growths.

The greater number of the growths included in the category of malignant are comprised in the group of carcinomata, and present the following varieties:—*Schirrus*, *encephaloid*, *scirrhus-encephaloid*, and *colloid*. Others belong to the epitheliomata, and not a few to the adenomata and lymphadenomata. The former are perverted growths of the epithelial tissue; but sometimes tumours of the sarcomatous or connective-tissue type are met with, following a malignant course, and presenting many points of similarity to *encephaloid*. The microscopic characters of these new growths present no special features. See *CANCER*, and *TUMOURS*.

As a rule, malignant growths would appear to commence in the mucous and submucous coats of the bowel, and then gradually involve the other tissues; but the colloid form usually begins in the peritoneum, and extends inwards.

The mesenteric glands are invariably affected, and may come to form large tumours.

Following the general course of these neoplasms when found elsewhere, they may undergo degeneration and ulceration, thus suffering a diminution in bulk at one spot whilst they extend

in other directions, and this is especially the case in the more rapidly growing varieties, as the *encephaloid*, *adenoid*, and *malignant sarcoma*. In the course of their development they may set up adhesions between the bowel and other parts, as the abdominal wall or uterus, and two or more coils of intestine may be thus involved.

The new-formed tissue may constitute an irregular mass of a very variable size and extent, of a nodulated or of a villous appearance, perhaps partially ulcerated, and extending into the passage of the canal, producing an obstruction. The *scirrhus* and *encephaloid* growths are liable to develop in an annular manner, involving the whole circumference of the bowel; the obstruction produced in such circumstances may be extreme, even to narrowing the lumen of the tube to barely the size of a probe. Occasionally, however, annular *encephaloid* growths occur with no stenosis, but rather a dilatation of the canal. The extent of obstruction may be altered by partial destruction of the new growth by sloughing, though the subsequent cicatrices that may result will again constrict the gut.

SYMPTOMS.—For a varying time before this disease definitely and unmistakably asserts itself, the patient complains of vague dyspeptic symptoms, a sense of uneasiness in the abdomen, not amounting to pain, and usually increased after meals, and marked irregularity in the action of the bowels, with or without flaccid distension. The persistent and gradual increase of these symptoms especially if there be any loss of flesh, is very significant and should excite suspicion.

Sooner or later, according to the duration of the case, the usual cachexia is established; and in the greater number of cases the patient rapidly emaciates, especially towards the end, though in cases of very short duration the wasting may not be so excessive. The emaciation depends not only on the general perversion of nutrition caused by the development of the cancer, but also on the direct influence it exerts on organs concerned in the digestion of nutriment.

The local signs and symptoms referable to the new growth itself are very variable in their occurrence, and often are singularly slight in comparison with the gravity of the cause. Thus pain may be completely wanting, and perhaps there is but little tenderness on pressure; when present the pain is usually of a dull character, and quite localised. When the rectum is affected, the pain is apt to be rather of a burning character, and to radiate into neighbouring parts; not infrequently in this situation the pain may be extreme, and with tenesmus may amount to a degree of suffering which is very rarely the case elsewhere.

The indications of the tumour produced by the new growth are very uncertain, being often little more than an ill-defined fulness in one region; at other times presenting a distinct hard irregular mass, of variable size, this last quality being partly dependent on faeces. Should the growth happen to be situated on the aorta or iliac arteries, an indistinct pulsation may be communicated to it. The percussion-note over the tumour is usually imperfectly tympanitic, from the existence of coils of intestines between it and the abdominal wall, the thickness of which will of necessity considerably modify the signs of the existence of

the growth. The mass may present all degrees from free mobility to complete fixity, dependent on the nature of its seat, and also on the existence of adhesions to neighbouring parts.

Symptoms of intestinal obstruction are rarely wanting; though, as already said, in exceptional cases the bowels may be dilated at the seat of the growth. Vomiting, constipation of increasing severity, with signs of intestinal distension above the lesion, are among the most constant; occasional diarrhoea, determined by the chronic enteritis which exists, may alternate with the constipation; and rupture of the intestines has been met with. See *INTESTINAL OBSTRUCTION*.

The stools are usually characteristic of the obstruction, consisting of small separate masses, frequently hard and round, and often mixed with sloughed-off portions of the new-growth, or with blood that has escaped from the ulcerated surface. The nearer to the anus the growth is situated, the less change will there be in the blood, which sometimes may be considerable in amount.

If the peritoneum be involved, peritonitis is likely to arise; and ascites, often considerable, is usually developed with colloid cancer. Superadded to these symptoms will be those caused by the morbid condition of any other organ that may be affected, such as the liver, bladder, or uterus.

COURSE AND TERMINATIONS.—Malignant disease of the intestines in the majority of cases progresses continuously from its commencement to a fatal ending. It is difficult to state even an average duration, owing to the insidious onset and vagueness of the first symptoms, but the greater number of cases rarely go beyond twelve to eighteen months from the time when the disease is clearly established, whilst some may be fatal in a few weeks, and a few may last for years.

Death may result as the direct consequence of the cachexia; or from hemorrhage, peritonitis, or other effects of the growth.

DIAGNOSIS.—An exact diagnosis is often not to be made, and the nature of the case remains throughout uncertain, if not actually as to the existence of a malignant growth, at least as to the seat of it. The insidious and ill-defined character of the earliest symptoms presents nothing diagnostic, though their progressive character and resistance to treatment would cause a suspicion, especially in a person over middle age, and in whom a gradual even though slight loss of weight is noticed. Even in the later stages, the symptoms are almost identical with those of chronic enteritis, which really co-exists with the new-growth to a greater or less extent; and in the not unfrequent cases in which a tumour is not to be felt, or is uncertain in its indications, the diagnosis becomes extremely difficult. Some cases also in which the new-growth is unrecognisable to palpation, and at the same time causes little or no obstruction, closely simulate in their course diseases of the supra-renal capsule; for the latter are not invariably accompanied by cutaneous pigmentation, and the rapid and progressive emaciation, with more or less persistent vomiting, may be common to both. It is true that the malignant cachexia is frequently productive of a characteristic *facies*, but this would equally occur in cancer of the capsule.

Supposing that the existence of an abdominal tumour be clearly ascertained, it is not always easy to determine its connection with the intestine, since the variability in position, in mobility, and in size (due to the accumulation, or the retence, of feces), precludes any diagnostic sign, although this very variability is regarded by some as almost indicative of intestinal cancer. In distinguishing between an intestinal tumour and one connected with the liver, pancreas, kidney, mesenteric glands, uterus; abdominal wall, or the inflammatory new-growths following a perityphilitis, an aneurism, or a simple fecal accumulation, the history of the case, age, progressive nature of the condition, existence of tumour, signs of obstruction, and character of the stools, are the points to be considered in forming a diagnosis. Any one or even two of these points might equally indicate other lesions, but taken collectively, they will usually justify the formation of an opinion. A rectal cancer, that is accessible to the touch or even to inspection, need offer no difficulty, but it is otherwise where it comes to distinguishing a duodenal growth from one strictly limited to the pylorus. The vomiting in the latter case is more persistent than in the former, and there is a greater liability to hæmatemesis; but these are most uncertain signs, as also is the existence of jaundice, which oftener complicates the duodenal affection, from the greater chance of involving or pressing on the bile-duct, but jaundice is not a necessary accompaniment. A firm epigastric tumour, felt close to the margin of the thorax, and associated with distinct dyspeptic symptoms, may also be due to primary cancer of the head of the pancreas. The symptoms of obstruction are less marked at first, but the growth will probably involve the gut in its progress, and cause more complete stenosis. Owing to the destruction of the gland-tissue, the pancreatic juice is not secreted, and undigested fat may be found in the stools.

Similar difficulties may surround the investigation of a tumour situated in the right iliac fossa. Emaciation, constipation, and melæna might equally indicate a scirrhus-encephaloid tumour of the cæcum, or the remains of a chronic perityphilitis. The history may help a little, but frequently the case remains throughout in doubt.

TREATMENT.—The extremely rare cases of reputed natural cure of malignant disease of the intestines, brought about by sloughing of the growth and subsequent cicatrization of its site, afford no hope of our being able to artificially imitate the process, and the treatment remains at the best symptomatic and palliative.

The diet should be so arranged as to contain the minimum of indigestible residue, and permit the chief digestion and absorption in the stomach, if it be the upper part of the tube that is affected. But in the majority of such cases the utmost disinclination for food exists, even apart from any vomiting or pain its ingestion may produce, and hence, whatever the directions, the patient in the later stages practically takes nothing. The anorexia is frequently as marked even when the mischief is seated in the colon, and the area for digestion and absorption is uninterfered with.

In the earlier stages it may be advisable to insert upon as much nutritious food as possible by the mouth or in the form of enema, so as to offer the most prolonged resistance to the inevitable end; but at the same time there is no slight cause for thinking that the same course favours the speedier development of the new-growth. Preparations of iron may be given with the same view.

The symptoms dependent upon the obstruction we can do next to nothing to relieve, only the mildest aperients are permissible, to combat the constipation; while the vomiting is as a rule uncontrollable, and, indeed, is often a relief.

Hæmorrhage may require special attention, and the pain may be so severe as to necessitate free administration of morphia subcutaneously; in other cases belladonna is of value in alleviating the local discomfort, and acts favourably by allaying any spasm. But our best remedies offer no resistance to the progress of the disease, and but too often very little relief.

The special characteristics of cancer of the rectum, sigmoid flexure, or cæcum occasionally permit of operative interference—such as colotomy. See **INTESTINAL OBSTRUCTION**, and **RECTUM, Diseases of**.

14. Intestines, Malpositions of.—Displacements of the intestines, like malformations, are both *congenital* and *acquired*.

Among the former may be mentioned complete transposition of the viscera, the cæcum and ascending colon being on the left side, and the sigmoid flexure and descending colon on the right, the liver, spleen, stomach, &c. sharing in the change. Certain parts only of the intestinal canal may occupy an abnormal situation, as seen in the various congenital herniæ, or the displacement may be due to unusual length of the mesenteries, the cæcum and sigmoid flexure being the parts that present the most usual alteration from this cause. Thus the cæcum may occupy the left hypochondrium or left iliac fossa, or be found in the pelvic cavity, and, of course, other parts of the canal must correspond to these malpositions. The sigmoid flexure has been seen lying to the right side of the left kidney, which was situated immediately below the bifurcation of the aorta. Similar displacements are referable to adhesions, determined by intra-uterine peritonitis, which is frequently associated with syphilis.

The malpositions which the intestines may come to present from changes set up after birth are so variable as scarcely to admit of classification. Hernia, both external and internal, volvulus, and intussusception are among the well-recognised displacements, but there is scarcely any limit to the changes in position which the traction and pressure of tumours and the effects of peritonitis may produce.

Many of these conditions give rise to no symptoms, and may even fail to be recognised during life. The acquired malpositions lead to obstruction in varying degrees. See **INTESTINAL OBSTRUCTION**, and **HEMIA**.

15. Intestines, Morbid Growths of.—Owing to the variety of tissues that enter into

the formation of the intestine, so less than to the origin of these tissues from two of the three primary layers of the blastoderm, the new-growths that may develop are exceedingly numerous.

It will be most convenient here to consider them from their clinical rather than from their genetic or histological point of view, and to divide them into *malignant* and *non-malignant* growths. The former have already been treated of, and the special neoplasms of tubercular and syphilitic origin are more conveniently referred to separately.

VARIETIES.—1. *Fibromata*. These growths, which are developed from the connective tissue of the submucous coat, are usually of small size, frequently pedunculated, though sometimes appearing as sessile, flattened nodules, of half the size of a pea projecting into the canal. The smaller ones may be scattered throughout the length of the bowel, whilst the larger ones (up to the size of a walnut) are fewer in number or single, and are usually found in the rectum. They present the ordinary microscopic characters of fibrous tissue.

2. *Lipomata*.—Polypoid growths of adipose tissue, springing from the submucous coat, are not of uncommon occurrence in any part of the intestines. Less often they are sessile and of small size.

3. *Myomata*.—Very rarely small growths are met with, chiefly composed of contractile fibro-cells, with a variable amount of connective tissue.

4. *Vascular tumours—Angiomata*.—Besides hæmorrhoids, other vascular growths are sometimes found, of an erectile character, similar to naevi of the skin.

5. *Mucous*.—It is to these growths that the term *polypi* is oftenest applied. They essentially consist of all the tissues of the mucous membrane, though differing in their vascularity, and also in their glandular elements. When these latter are excessive in amount, they are liable to present characters which connect them with malignant forms of new-growth, especially if their surface assume a villous character. Polypi are not limited to any one part of the canal, though undoubtedly they are most common in the rectum. Sometimes they are distinctively pigmented. They are occasionally multiple; and have been met with at all ages.

6. *Lymphoid growths—Lymphadenomata*.—Neoplasms whose structures correspond to that of the solitary or agnate glands, or of the lymphoid layer of the submucosa, are met with in association with these normal constituents of the intestinal wall, and quite independently of any leucocytæmia.

7. *Cysts*.—These have been rarely met with, and the contrast to their comparative frequency in the uterine mucous membrane is remarkable. Dr. Dickinson (*Tr. Path. Soc.* vol. xii. p. 138) records the occurrence of a colloid cyst of the size of an orange, between the muscular and mucous coats of the cæcum in a patient aged 75, so placed as to give rise to no obstruction or other symptoms. The contents were gelatinous and oily, and there were no cysts elsewhere.

EFFECTS AND SYMPTOMS.—As a rule, the growths mentioned above present very little interest, unless they be situated just within the

rectum, and accessible to digital examination. They cannot be diagnosed, though they may give rise to certain symptoms, as, for instance, hæmorrhage from the vascular polyp and erectile tumours, or partial obstruction if they attain any size; but such symptoms are not diagnostic. One of their most interesting effects appears to be the liability that the polypoid forms, occurring in the small intestine, have of inducing intussusception, from interfering with the due progress of peristalsis. Prolapse of the rectum is similarly found to be occasionally due to polyp.

TREATMENT.—No treatment can be attempted, beyond that of the symptoms which may arise; or the removal of growths within reach of the anus.

16. Intestines, Paralysis of.—The peristalsis of the intestinal tube is normally dependent on automatic nerve-impulses, originating in the intrinsic ganglia of the canal, controlled by both reflex and direct impressions from the cerebro-spinal and sympathetic systems, the former acting *via* the vagus in an accelerating manner, the latter *via* the splanchnics in an inhibitory direction. The integrity of the involuntary muscular fibre is assumed.

ÆTIOLOGY AND PATHOLOGY.—A paresis of the intestinal movements may be brought about by (1) causes acting through the *nervous system*; or (2) through imperfection of the *muscular tissue*.

(1) *Nervous*.—Whilst it is possible that the intrinsic ganglia and nerves of the intestinal muscular coat may be the seat of degeneration, no known observations are recorded. Certain lesions of the brain are accompanied by symptoms of intestinal paralysis, but with no hitherto recognised regularity, and it is assumed that such lesions act by interfering with the function of the vagi. It is doubtful how far disease of the spinal cord produces actual paralysis of the intestines, though constipation may result, a circumstance that may be explained by assuming an interference with the centre that controls defæcation. See *ÆCCEA*, Retention of.

(2) *Muscular*.—The irritability of the muscular tissue may be much weakened by degeneration (cloudy, fatty, or amyloid). Inflammation of the mucous or serous coat, especially the latter, is liable to determine granular change in the muscular fibres, which, aided by a coexistent œdema, largely impairs the contractile power of the tissue. The irritability is also liable to suffer from the over-stimulation of too powerful and too frequent purgative medicines; and the muscular fibres of a much dilated portion of the bowel are apt to become paralysed from distension and stretching. The general want of tone that the muscular and nervous systems manifest subsequent to debilitating diseases, want of food, hysteria, and other conditions, also finds expression in the alimentary canal, in diminished peristaltic action.

The *modus operandi* of certain astringent drugs upon the bowel is quite unknown, possibly through the nervous system, as appears to be the case with opium, and perhaps by affecting the muscular fibres or nerve-terminals. Lead, which would seem to cause both paralysis and spasm of the muscular coat, may act in this way.

SYMPTOMS.—The prominent symptom of intestinal paralysis is constipation, though other signs of obstruction, such as vomiting, meteorism, &c., may be superadded. See *CONSTIPATION*; and *INTESTINAL OBSTRUCTION*.

TREATMENT.—As a rule this is directed to the primary cause, but great benefit has undoubtedly followed the special application of electricity to the abdominal parietes. Friction applied on systematic principles is of undoubted service.

17. Intestines, Perforation and Rupture of.—**ÆTIOLOGY.**—The causes of perforation or rupture of the intestines may be arranged thus:—1. *External injuries*, such as blows, being run over, &c., though more liable to rupture the solid abdominal viscera, frequently cause the intestines to burst, especially the ileum or jejunum.

2. *Corrosive poisons*, when swallowed in any considerable amount, may destroy not only the walls of the stomach, but also of the upper part of the intestines.

3. *Extreme distension by flatus* above the site of a constriction may cause the bowel to burst.

4. *Ulcerations*, pre-eminently the so-called peptic ulceration, and less commonly typhoid and catarrhal ulceration, are liable to lead to perforation.

5. *Perforations* may be produced *ab extrâ*, by the bursting of abscesses or aneurisms into the canal.

SYMPTOMS.—The most striking symptom which perforation of the bowel presents is collapse, and it is a noticeable fact that rupture of the hollow abdominal viscera is more liable to induce this condition than a similar lesion of such organs as the liver or spleen. The exact explanation of this collapse is not apparent.

Should the patient live twenty-four hours after the establishment of a perforation, signs of peritonitis will assert themselves—severe abdominal pain and tenderness, pyrexia, vomiting, and other symptoms. Supposing that the perforation follow an ulceration in the course of a previously high temperature, such as enteric fever, there will be a sudden and usually considerable fall in the body-heat; this may be the first indication that perforation has taken place.

Perforation or rupture of the intestines usually proves fatal within forty-eight hours of its occurrence, although cases are recorded which have lasted for weeks; very rarely recovery has taken place.

There are no reliable signs whereby rupture of the stomach may be distinguished from that of the intestines, nor is it of any practical importance. But the collapse and fall in temperature, with the history of the case, are quite sufficient to warrant the diagnosis of perforation of some part of the canal.

TREATMENT.—Rest is of primary importance, both in regard to the whole body, and the bowels themselves. This object is best attained by the free use of opium, commencing with a grain, and repeating it in a few hours until its influence is fully established. It is also desirable to cut off all food, except an occasional teaspoonful of meat essence; to give ice to suck; to administer nutrient enemata, and brandy and other if the col-

lapse be profound, and to apply warmth to the extremities.

18. Intestines, Spasm of.—The irregular and forcible movements of the bowels, usually accompanied with pain, are known as *colic*. Under ordinary circumstances we are unconscious of the peristaltic action, but when the contractions of the muscular coats become violent, more or less pain is likely to occur.

Ætiology.—The determining causes of intestinal spasm are:—

1. The direct irritation of indigestible ingesta. 2. Exposure to cold. 3. Certain poisons—lead, strychnia, &c.—which probably affect the muscular fibres through the nervous system.

It is difficult to ascertain the exact condition of the contracted bowel, since the appearances seen after death are not an index of what existed during life; but it would seem that the spasm may start from several points in the course of the canal, and, after persisting for a variable time, either yield or travel on as a wave of spasmodic contraction. For how long a portion of bowel may remain contracted is quite conjectural.

Symptoms.—The existence of a painless spasm of the intestines is very doubtful, as a rule it is the pain which indicates this condition, and except the contraction be maintained, no further symptoms may occur. Constipation, vomiting, meteorism, may all be present in varying degrees, dependent upon the extent of obstruction which is produced. Not infrequently fever, collapse, and prostration may co-exist, leading to the belief that a more serious condition is calling for treatment.

The specially painful spasm of the anal sphincters and lower portion of the rectum termed *tenesmus*, is associated with gouty congestion, with ulceration, and with most other lesions in that locality.

Treatment.—The external application of moist heat in the form of poultices or fomentations, profusely of poppy-head or other opiates, is of great value, for relaxing the spasm or removing the pain. Since an irritant is so frequently the cause, an aperient, such as castor oil or calomel, combined with opium, is essential. The collapse may be so severe as to call for energetic stimulation by brandy, ammonia, or ether.

19. Intestines, Syphilitic Disease of.—The intestinal canal is rarely the seat of the specific lesions of syphilis, except at the lower end of the rectum, and margin of the anus. Small gummata have been found in the submucous tissue of various parts of the bowel, but more often the ulcers to which these growths give rise by their degeneration and breaking down, radiating fibrous cicatrices of the mucous membrane have also been seen, produced by these syphilomata. It is doubtful whether there be any specific ulceration of the intestine which is not preceded by gummata, although small ulcers do occur in newborn children the subjects of congenital syphilis.

Syphilitic ulceration and stricture of the rectum is not of infrequent occurrence. See **RECTUM, Diseases of**.

20. Intestines, Tubercular Disease of.—The specific lesions of the tubercular diathesis,

namely grey granulations or miliary tubercles, are of frequent occurrence throughout the intestinal canal. Regarding them as local developments of lymphoid tissue, the opportunity for their formation is most favourable, owing to the extensive distribution of this tissue throughout the submucous coat, and the special aggregations of it which form the solitary and agminated glands. The abundant supply of lymphatic vessels in the thickness of the walls of the canal, and the close connection of the serous surface with the lymphatic system, all predispose to the development and spread of a tubercular growth which may have become established in a subject of the diathesis.

Ætiology.—As a primary growth tubercle very rarely attacks the intestines in adults, though it is of very frequent occurrence in children as part of a general tuberculosis. In adults, on the contrary, tubercular disease of the intestines is very commonly developed secondary to a similar affection of the lungs.

Anatomical Characters.—The submucous layer and the peritoneal coat are the structures in which the tubercle originates; in the former situation it especially favours the ileum and cæcum, although it may develop throughout the entire length of the tube, whilst the peritoneal tubercle is about equally distributed. The mesenteric glands are always considerably involved. The rareness with which the stomach is affected by tubercle is in marked contrast to the frequency of the intestinal lesion.

In extreme cases of tuberculosis in children, death may take place before any changes in the tuberculous formation have taken place, and countless grey granulations, from the size of a pin's head to bodies microscopic, are to be found in the submucosa, and in the solitary and agminated glands. Later on, however, these non-vascular new-growths coalesce, and form distinct masses, which from lack of nutrition undergo caseous degeneration and break down, thus forming the tubercular ulcers. The ulcers tend to spread, and rarely to heal, and whilst they may be at first limited to the glands, they invade the adjacent mucous membrane, especially in a direction round the bowel, their extension being preceded by the development of fresh tubercles, to the progressive formation and destruction of which the spread of the ulcer is really due. Large masses of the mucous surface may be thus destroyed, leaving a ragged flocculent surface, formed of the muscular fibres, or even of deeper structures, which lesions rarely proceed to perforation into the peritoneal cavity, adhesive peritonitis having established attachments to adjacent parts. The thickened, congested, irregular edges of the ulcers, with miliary tubercles close to the margin, are very distinctive; apart from the granulations, the ulcers themselves are not unlike those of dysenteric origin, or chronic follicular ulceration.

Symptoms.—Until ulceration be established, there will be no symptoms of tubercular disease referable to the intestinal canal, and even when this stage is reached, there is nothing to distinguish it from ulceration due to other causes. There is the same pain and tenderness, often but little marked, usually an obstinate diarrhoea;

characteristic stools with occasional blood; and progressive emaciation. Added to these are the symptoms due to implication of other organs—lungs, brain, &c.—since tubercular ulceration of the bowels scarcely ever occurs alone.

TREATMENT.—Little can be done for intestinal tuberculosis. The course of the disease is almost invariably to a fatal end, and it is very rare for healing and cicatrization to take place. The necessity for feeding the patient is almost contraindicated by the existence of a destroyed digesting and absorbent surface, whereby the food becomes a positive irritant. Such nourishment as is taken should therefore be in the most digestible and concentrated form, that as much as possible may be taken up from the stomach. Starch and opium enemata may do a little to check the diarrhoea, but their efficacy is soon lost. Hemorrhage, should it set in, is scarcely amenable to treatment, though nutritive enemata may be of some use, combined with the internal administration of acetate of lead and opium. No treatment has as yet been effectual in arresting the spread of tubercle, and until that be gained, there is nothing we can do that will permanently benefit the affected intestines; even palliative measures afford but little relief.

21. Intestines, Ulceration of.—Ulceration of the intestinal wall, from one cause or another, is of extremely common occurrence. The morbid processes involved in the production of the ulcers are in all cases essentially the same, namely, a molecular death and disintegration of the tissue, leaving a solution in continuity, of varying extent. The severe disturbance of tissue-nutrition which leads to ulceration, may be one of the later stages of inflammation:—(1), affecting previously healthy tissues; or (2), as a means for the removal of necrosed tissue; or (3), developed in new-growths.

VARIETIES: 1. Primary inflammatory ulcers.—Any enteritis, whether of the mildest character, or of a specific type such as diphtheritic, may lead to ulceration of the bowels. As a rule, the more severe the cause of the inflammation, the greater the liability to this complication, and the same holds in respect of any intestinal catarrh, developed in the course of any serious state, such as typhus fever or Bright's disease. The ulcer may appear either as a small abrasion of the epithelial layer, which gradually extends and deepens until the whole mucous coat is involved; or the first indication may be a thin glairy pellicle, adherent to the mucous membrane, which in time is thrown off, leaving a breach in the subjacent tissue. In other cases the destructive process commences in the thickness of the bowel, either from the rupture of small collections of inflammatory products, resulting from an enteritis, or from inflammation of the follicles. The escape of these products into the tube leaves behind an ulcer.

These lesions may be found anywhere throughout the bowels, although they are much more frequent in the large than in the small intestine, and one form of follicular ulceration, associated with the specific poison of dysentery, is practically limited to the latter situation. At those places where any delay is likely to arise in

the passage of the faeces—the caecum sigmoid flexure, and rectum—and at those spots which are most prominent, such as the edges of the valvulae conniventes, and the sacculi of the colon where an enteritis is most likely to be produced, here will be the probable site of these inflammatory ulcers.

2. Ulcers resulting from the separation of necrosed tissue.—The process of molecular disintegration which takes place in the adjacent bodies of living and dead tissue, resulting in the separation of a slough and the leaving of an ulcer, takes place in the intestines as elsewhere. The causes leading to the death of circumscribed areas of tissue are various. Sometimes the vitality of a portion of the mucous membrane is destroyed by degeneration, such as amyloid, and an ulcer marks the spot of the removed patch. More frequently the local death is induced by cessation of blood-flow through a limited area, the cause of this stasis is not very apparent, though believed to be due to emboli. Under such circumstances the solvent power of the digestive juices may be exerted on the non-living tissues, which are thus removed, and an ulcer is left. To such ulcers the term *peptic* has been applied, and identical lesions are met with in the stomach. They almost invariably occur in the first part of the duodenum, above the point of entrance of the alkaline bile and pancreatic juices, although very rarely they have been seen in the jejunum. Ulcers of this character appear to be connected with large superficial burns, but how the relationship is established is not known. It is a singular fact in regard to them, that they are ten times more common in men than in women, which is quite the reverse of what obtains in the stomach, although the relative frequency of gastric and duodenal ulcers is estimated as thirty to one. Both the ileum and colon have been found ulcerated in amyloid degeneration.

3. Ulceration of new-growths.—Almost any neoplasm of the intestinal wall may ulcerate, though as a rule the more rapidly developed forms are more liable. Tubercular and typhoid growths primarily connected with the solitary and agminated glands, invariably end in this manner. Syphilitic gummata and malignant growths are especially prone to ulceration.

CHARACTERS.—The appearances presented by the various ulcers differ with the cause and the duration.

They may be single, as is generally the case with the duodenal ulcers, or innumerable, as the follicular ulcers of the colon. Typhoid and tubercular ulcers are as a rule multiple, and are most numerous at the lower end of the ileum, where the agminated glands are most abundant. Occasionally large surfaces of the mucous membrane are destroyed, with here and there small isolated spots of the membrane left, due to the spread and coalescence of many separately arising ulcers. In dysentery and chronic tubercular ulceration this is especially liable to happen. Many of the catarrhal and follicular ulcers are extremely small, not more than a line in diameter.

The peptic ulcers are distinguished by their very definite, 'clean-punched' appearance; the edges are slightly sloping, and but very little,

if at all, thickened, whilst the mucous membrane immediately adjacent has a perfectly healthy appearance. In most of the other varieties the edges are thickened, irregular, and shaggy, frequently excavated and overhanging the base; the ulcerative process extending beneath the mucous membrane, which gradually dies and sloughs away as its nutrition is cut off. Dependent upon the depth and course of the ulcer will be the nature of its base, which may be formed of the muscular coat, of the peritoneum much thickened, or of adjacent structures with which adhesion has been established, such as the liver or abdominal wall. The floor of the ulcerated tubercular and malignant new-growths usually presents small nodules of the neoplasm, which are being developed coincidently with the ulceration. The buff or ash-grey pigmented sloughs, partially separated, give a characteristic appearance to the old-standing ulcers of dysentery and tubercle. The tubercular and typhoid ulcers of Peyer's patches present a certain difference in the direction in which they extend; whilst at first both are limited to the patch, the former tend to spread in an annular manner, whilst the latter have usually their long axis corresponding to the length of the bowel. This difference depends rather on the duration of the ulcer, than on any specific distinction due to the two diseases, for the more acute enteric lesion rarely spreads much beyond the area of the patch, which is in the long axis of the bowel, whilst the chronic tubercular ulcer follows the distribution of the lymphoid tissue outside the patches, and particularly along the course of the blood-vessels and lymphatics.

COURSE.—The course of an intestinal ulcer may be acute or chronic, lasting a few days or for years. Some of the simple ulcers of an acute intestinal catarrh belong to the former group, whilst the ulceration that accompanies chronic enteritis may be of indefinite duration.

The acute forms may either heal or go on to perforation; in the former case their existence can only be inferred, and catarrhal and follicular and enteric ulcers belong to this category. The peptic and typhoid ulcers are those most liable to perforate the gut, their duration being too short to allow of the formation of adhesions to neighbouring structures, as is very apt to be the case in the more chronic forms. Occasionally the perforation may lead to communication between one coil of intestine and another, between the duodenum and stomach, or between the bowel and bladder, without any rupture into the peritoneal cavity, which is the commonest end of a perforating typhoid ulcer. In chronic ulcers, where no adhesion or communication takes place, the base is thickened by a new-formed connective tissue, which is developed as fast as or even faster than the destructive process proceeds, and hence the intestinal wall adjacent to, and involved in such ulcers, is usually much thickened and indurated. Short of actual perforation or adhesion to other parts, the site of the ulceration most frequently is marked on the external surface of the bowel by a sub-acute peritonitis, which may produce a partial matting together of the intestines.

In the course of the healing of the larger

ulcers, by the formation of a contracting cicatricial tissue, the gut may be considerably constricted, and a most formidable obstruction may be established. But this does not necessarily follow even large ulcers, such as those of typhoid fever, and the extent of depth of the destruction would seem to influence this result, when the superficial portion of the mucous membrane only is destroyed very little contraction follows, but when the deeper parts of the wall are involved the subsequently developed cicatrix tends to shrink considerably. Similar differences are seen in destructions of the skin and subcutaneous tissues.

SYMPTOMS.—The greatest diversity is met with in the symptoms of intestinal ulceration, and few, if any, can be regarded as characteristic. Inasmuch as the lesion may occur without producing any symptoms; or those that do exist may be determined by the course of, or by the conditions associated with the ulceration; or lastly, the results of this condition, such as perforation, may entirely obscure the actual ulceration itself. It frequently happens that the existence of an ulcer is not recognised. Nor may the severity of the symptoms be taken as a measure of the extent of the ulceration, for the most marked pain, tenderness, diarrhoea, and other symptoms may be produced by an area of typhoid ulceration that heals; whilst a perforating duodenal ulcer may give scarcely any indication of its existence, until within a few hours of a fatal ending. This course appears to be very characteristic of duodenal ulcers; and the writer has recorded a case of a young man who was suddenly attacked with all the symptoms of apparently intestinal colic, after constipation of a week's duration, no vomiting and no tenderness, the pain being relieved by pressure on the abdomen. Collapse set in, and death resulted in less than twenty-four hours from the commencement of the attack. The autopsy showed a perforating duodenal ulcer. Such a case is not singular, and may be preceded, as this case was by nothing beyond an occasional feeling of discomfort at the epigastrium, not serious enough to call for advice or treatment.

Such symptoms as diarrhoea, vomiting, pain, tenderness, and pyrexia are as much dependent on a co-existent enteritis or new-growth, as they are upon the ulcer. Doubtless the exposed surface of an ulcer offers the opportunity for increased peristalsis being induced, but this is not of necessity, for constipation may be present. Where the area of ulceration is extensive, the absorbing surface is by so much diminished, and thus while the general nutrition suffers, the unabsorbed products of digestion are liable to decompose and induce diarrhoea. Vomiting may arise from a duodenal ulcer, but not always, and when present it may be due to peritonitis; tetanus may also complicate an ulcer in this situation, by involving the opening of the bile-duct, or by extension of the duodenal catarrh. Pain may be quite absent or quite insignificant, unless the rectum be the seat of the disease, when the pain and tenesmus are excruciating.

The passage of blood in the stools, especially if bright, is probably a most characteristic indication of ulceration, but it does not always

occur, and it may be due to general venous congestion from partial obstruction. See STROOLS.

The symptoms due to perforation have been already described. See INTESTINES, Perforation and Rupture of.

Diagnosis.—From what has been said, the formation of a diagnosis of intestinal ulceration is frequently impossible, and an ulcer is assumed rather than proved to exist. In enteric fever ulceration is taken for granted as existing, though no special symptoms may indicate its presence. But if a severe and persistent diarrhoea, with liquid stools and shreds of mucus, and much pain and tenderness over the abdomen, supervene in a case of tubercular phthisis, it is a fair inference to assume ulceration of the intestines. In dysentery, like enteric fever, the ulceration is a specific part of the disease, and the diarrhoea, pain, and characteristic stools are in this case directly dependent upon the ulceration. Since there are no constant distinctive symptoms of ulceration, the ground for a diagnosis must remain uncertain.

Prognosis.—This largely depends upon the cause. Except through perforation or fatal hæmorrhage by erosion of vessels, death does not take place from the ulceration itself. But a tubercular ulceration is not to be expected to heal, and it may by its development hasten the end of a phthisical patient. The prognosis in typhoid ulceration will almost entirely be founded on the general state of the patient, since the indications of the ulceration itself may be so slight. The ulceration of malignant new-growths may be of actual benefit, by removing portions of the mass, and so diminishing obstruction. In all cases the liability to stenosis must be remembered; and the impaired health of body and mind in chronic ulceration may continue throughout life.

Treatment.—Since ulcers of the intestine are inaccessible to direct treatment, little can be done for them apart from the general conditions which they may complicate, or the treatment of the symptoms to which they may give rise.

Recognising that an ulcer, when it exists, may lead to perforation, the object will be to avoid all undue movements of the intestines, and hence aperients are forbidden, and opiates are indicated. The astringents that are likely to be used for the diarrhoea or hæmorrhage may exert a local action on the lesion, and for that purpose bismuth, sulphate of copper, and similar agents, are recommended. But rest is probably the only element of treatment that can affect the ulcerative process directly; whilst any improvement of the general condition will necessarily favour the healing—objects which can be best accomplished by the use of dist of the most bland description, or of nutrient enemata.

In the preceding article the diseases to which the intestines are liable have been treated of as affecting the canal as a whole: but it will be observed that when the structure and functions of particular regions of the bowel modify the character of the disease, special reference is made thereto; and, further, that when the affections of any portion require detailed description—as of the cæcum or rectum, the reader is referred to articles under those headings.

WILLIAM HENRY ALLCHIN.

INTRA-THORACIC TUMOURS—Under this general term are included all growths and diseases within the chest, which give rise to tumours or swellings, offering more or less mechanical interference with the functions of the thoracic organs, and for the most part manifesting themselves by external swellings. Aneurisms would thus be comprised in this general definition. The general features and pathology of aneurismal tumours are, however, so distinct as to require separate consideration (see THORACIC ANEURISM). Other intra-thoracic tumours will be found described under the headings LUNG, Malignant Disease of, and MEDIASTINUM, Diseases of.

J. RUSKIN BENNETT.

INTUSSUSCEPTION (*intus*, within, and *suscipio*, I receive).—A form of intestinal obstruction, in which one portion of the bowel passes into another portion. See INTESTINAL OBSTRUCTION.

INUNCTION (*in*, on, and *unguo*, I anoint). **SYNON.** Anointing.—This is a method of applying certain substances to the cutaneous surface, the object being to promote their absorption, either for the purpose of producing local effects, or of influencing the system generally. Inunction implies more or less friction, the substance employed being rubbed with the hand into some part of the skin. When used for local purposes, the part to be anointed must be chosen accordingly, but if it is intended to affect the system, a region must be selected where the cutaneous tissues are thin, such as the inside of the thighs, or the axillæ, so that absorption may take place more rapidly and easily. The rubbing must be carried on gently, and for a variable time according to circumstances, it may be aided by heat, being performed before the fire, or the part may be previously fomented.

APPLICATION AND USES.—The pharmaceutical preparations which are employed for inunction include glycerines, liniments, oils, ointments, oleates, and compounds made with vaseline, ozokerine, and other materials of a like nature recently introduced. If these are used for local purposes, they may be employed simply on account of the oleaginous ingredients, or to allow friction to be more easily carried on, but active ingredients are often combined in the preparations mentioned above, varying according to the object sought to be obtained, such as to produce a stimulant or an anodyne effect. Inunction for procuring absorption in order to affect the system, is almost entirely confined to the use of mercury, and on this subject the following observations were written for this work by the late Mr GURCOVEN—

‘Inunction is an old but very effectual plan of introducing mercury into the system by the skin. Although objected to as a dirty method, and therefore less practised than fumigation, it is often much more convenient, and can be used in many cases where the mercurial bath is impracticable.

‘From half a drachm to one drachm of strong mercurial ointment, mixed with an equal quantity of lard, should be rubbed into the skin on the inside of the thighs, legs, and arms, before a fire at bedtime, using the different limbs on successive nights. The friction should be gentle

and continued for a quarter of an hour to half an hour, when most of the ointment will have disappeared; the surface must not be washed, and the patient should wear the same flannel under-clothing night and day. The ointment may be used every night until the gums give evidence of its action, when the quantity and frequency of application must be diminished. Sometimes it will produce an irritation of the skin, especially in fair or hairy persons. If this occur, the surface must be washed clean, and the rubbing discontinued.

Inunction is a most convenient way of treating syphilis in young children. The ointment should be spread upon a flannel roller, and the body of the child swathed therein; occasionally the skin should be washed, and fresh ointment applied.

Although but little practiced now in this country, inunction is still largely employed on the Continent, and particularly in conjunction with the natural sulphur waters, for cases of old-standing syphilis. FREDERICK T. ROBERTS.

INVAGINATION (*em*, in, and *vagina*, a sheath).—A synonym for **INTUSSUSCEPTION**. See **INTUSSUSCEPTION**; and **INTESTINAL OBSTRUCTION**.

INVASION, Modes of.—This expression signifies the manner in which a disease sets in or commences, and the mode of onset of an illness is frequently an important factor in forming a diagnosis as to the nature of the complaint. The following are the variations noticed in this respect:—1. The invasion may be absolutely or almost sudden, although slight symptoms may have been previously observed, indicating the presence of some morbid condition, but not sufficiently marked to attract attention. Or there may be distinct indications of some disease, but a secondary lesion suddenly occurs in its course. This mode of onset is exemplified by the immediate effects of injuries, apoplexy, syncope, rupture of the heart, cholera, many cases of hemorrhage, and most forms of colic. Certain diseases of a paroxysmal type are also characterized by the occurrence of attacks, which come on more or less suddenly, such as asthma, ague, and epilepsy. Some cases of fevers, especially typhus and relapsing fever, as well as of inflammatory diseases, begin in a sudden manner. 2. Frequently the onset is *acute*, the symptoms coming on rapidly, and becoming speedily severe, though often preceded for a variable time by premonitory symptoms. This is illustrated by most cases of the various fevers, and the different forms of acute inflammation. 3. A *subacute* mode of invasion is not uncommonly noticed, this being less rapid, and the symptoms less marked than where it is acute. 4. Most affections are *chronic* in their onset, setting in gradually, and often imperceptibly, so that it may be a long time before the patient is aware that there is any deviation from health. FREDERICK T. ROBERTS.

IODISM.—**DEFINITION**.—Iodism is the term within which we include a variety of painful and morbid effects, following, under certain rare circumstances, the administration of iodine and its salts, but more especially the iodide of potassium.

DESCRIPTION.—Iodide of potassium being in part, at least, decomposed in the presence of ozone by the acids of the blood, we shall endeavour, in considering the symptoms of iodism, to determine which are due to the iodine, and for which the potash must be held responsible. The physiological action of iodine is mainly directed to the nutritive and glandular functions, to the skin and mucous membranes; whilst the salts of potash are not only diuretic and purgative, but, experimentally at least, powerfully depress the heart and spinal cord.

Rilliet, the most exhaustive writer on the subject, makes three forms of iodine intoxication: the first consisting of gastric irritation; the second, where nervous troubles come into more special prominence, whilst cachexia and rapid emaciation characterize the third. But the most orderly and convenient plan to pursue, will be to take into consideration, in regular order, the effects produced by iodine salts on the various organs and functions of the body, under various conditions of idiosyncrasy or retarded elimination.

1. *On the nervous system*.—Mental depression and diminution of muscular energy are not infrequently noted in patients taking iodide of potassium, whilst neuralgia, tinnitus aurium, and convulsive movements have also been described. It is probable that the potash is here the active agent.

2. *On mucous membranes*.—Much mucous irritation is occasionally observed; conjunctivitis, lachrymation, sneezing and running from the nose, frontal headache, and puffy swelling of the eyelids, closely simulating coryza, being the most common symptoms of iodism, and sometimes following a single small or moderate dose. Pharyngeal congestion, and irritable redness of gums and tongue, have also been described. These symptoms are doubtless due to the iodine.

3. *On the skin*.—The eruptions produced by iodide of potassium have recently attracted much attention, and they appear under several forms. Erythema has been observed; and most practitioners of experience must have seen the small round pitechial spots, situated between the knees and ankles. These do not as a rule cause any inconvenience, and are usually accidentally discovered; but Dr. Stephen Mackenzie records the case of an infant of five months old, suffering from hereditary syphilis, who died of purpura after taking two and a half grains of iodide of potassium in a single dose. Some further points of interest, in connection with a case of this kind, reported by Dr. G. F. Duffey, will be found in the *British Medical Journal*, 1880, vol. 1. p. 626.

A papular and pustular eruption resembling acne, and occasionally appearing in so great profusion as to excite the suspicion of small-pox, is not very uncommon. The late Dr. Tilbury Fox has noted 'a quasi-bullous disease,' summing up the description of his cases as follows: 'In some parts they resembled acne simplex; in others they vesiculated and subsequently stimulated variolous pustules; at a later stage ecchyma; finally bullæ filled with milky contents, or discharging serous; and these bullæ possessed peculiar solid bases wholly unlike true bullæ.'

and answering rather to large molluscum contagiosum tumours with semi-fluid instead of more solid contents.

Dr. Fox believed this condition to be essentially distinct from hydrops, but Mr. Hutchinson has brought forward good evidence to show that the rare skin-affection going under that name must usually be looked upon as one of the symptoms of iodism. The same author mentions a case of deep and unhealthy ulceration of the legs following the prolonged use of iodide of potassium. It seems probable that the iodine rather than the potash must be held responsible for these symptoms. See *Archives of Dermatology*, 1880.

4. *On the nutritive and glandular systems.*—Patients taking iodide of potassium sometimes complain of nausea, anorexia, and a bitter taste in the mouth; but where cachectic symptoms supervene, indicated by rapid emaciation, nervous palpitation, insomnia, and hypochondriasis, a ravenous desire for food has been observed. Vomiting, diarrhoea, and diuresis have also been described. Salivation is not an uncommon symptom. A time-honoured accusation against iodine is its supposed tendency to cause atrophy of the mammae and testicles; of this, fortunately, there is no real proof, the disappearance of the testicle, which occasionally accompanies the absorption of inflammatory products in its substance, being sometimes unjustly attributed to the treatment pursued.

PATHOLOGY.—The only reason for the occurrence of many cases of iodism seems to be an individual peculiarity on the part of the patient, or in other words, that idiosyncrasy which so frequently interferes with our efforts for the treatment of disease. But now and then a more plausible explanation may be given, when we find cardiac or renal disease coinciding with the pustular rash of iodide of potassium. Retarded capillary circulation would naturally detain the drug within the blood; whilst the blocking of its usual means of exit from the system might be supposed to throw the onus of elimination on the glandular structures of the skin. Hence has been derived the plausible theory that iodine-acne is produced by direct local stimulation of the sebaceous structures; but, however true this may be in the slighter cases, Dr. Thén's careful examination of the skin of a patient suffering from a bullous rash, has shown the true pathological condition to be one of rupture of blood-vessels at certain localised points, with blocking by coagula, and escape of some of the constituents of the blood into the surrounding tissues. The sebaceous elements and sweat-glands were quite unaffected, and he believes the iodine papule, the so-called acne, the bulla, and the purpuric spot, to represent different stages of vascular injury. Drs. Duckworth and Vincent-Harris were unable in their observations to detect any rupture of vessels, but confirm Dr. Thén's report in all other essential respects.

DIAGNOSIS.—Coryza, or any skin-eruption, suddenly occurring in a patient taking iodide of potassium, ought to be looked upon with suspicion, and treated by the immediate suspension of the drug. The slightest varieties of iodism are by no means uncommon, and may appear after a single small dose; but although anomalous has

been confidently vaunted as a specific against such irregular manifestations of physiological activity, experience has been unable to confirm this, and we should place more faith in encouraging prompt elimination by very free dilution of the remedy.

Fortunately, the graver symptoms of iodism are decidedly rare, and we may all the more congratulate ourselves on this, when we remember how powerless we are to recognise the idiosyncrasy on which they depend. Trousseau, however, pointed out that iodine is always badly borne in exophthalmic goitre; and Dr. Stephen Mackenzie is inclined to credit syphilis with some share in producing the purpura which proved fatal to his patient.

ROBERT FARQUHARSON.

IRELAND, South of. See QUEENSTOWN. Glengriff is also deserving of notice.

IRITIS.—Inflammation of the iris. See EYE AND ITS APPENDAGES, Diseases of.

IRREGULAR.—This term is applied to cases of disease which do not run their regular or typical course, such as gout (see GOUT); or to functions when they are disturbed with respect to time or rhythm—as the pulse, the bowels, or menstruation.

IRRIGATION (*irrigo*, I water).—A method of applying cold water as a therapeutical agent, which consists in causing it to fall drop by drop on one spot. See COLIC, Therapeutics of.

IRRITABILITY (*irrito*, I provoke).—In physiology this word signifies the power of responding to a stimulus, as exemplified by the contractility of muscular tissue. In medicine irritability implies an undue excitability of an organ or tissue, from disease or disorder, such as of the brain, spinal cord, stomach, eye, or bladder.

IRRITATIVE FEVER.—The nervous disturbance consequent upon fretting of the system by various sources of irritation, gives rise to a pyrexia which is often called 'Irritative fever.' The febrile excitement so familiar to the surgeon as a consequence of wounds and injuries may be classed under this head. It may, however, be provoked by any kind of irritation, especially irritation applied to the mucous membrane of the alimentary canal. The rise of temperature which often accompanies irritation of the bowels by scybala or acrid secretions, and the febrile phenomena attendant upon dentition, may be quoted as familiar examples of irritative fever which must be within the experience of all.

The readiness with which pyrexia can be induced by these and similar causes must vary according to the intensity of the irritant, and the constitutional peculiarities of the individual upon whom it operates. As a rule, men are less susceptible than women, and women than children. In children, indeed, with their exalted nervous sensibility, feverishness from this cause is a common symptom. In young subjects mental emotion alone will often produce a rise of temperature, which may be a source of perplexity. In children's hospitals it is a common

observation that the bodily temperature on the night of admission is high, even although the illness affecting the child is one not in itself usually accompanied by fever.

Dilatation in young children is so frequent a cause of pyrexia, that the state of the gums should never be overlooked in any case where restlessness is a prominent symptom. Neglect of this precaution may cause some obscurity in the diagnosis. Thus, if a child, while cutting a tooth, have an attack of pulmonary catarrh, the temperature will almost certainly be high. In such a case the cough, combined with fever, rapid breathing, and a quick pulse, might naturally suggest the presence of pneumonia. On examination, however, it will be found that the pulse-respiration ratio is little perverted, the cough is loose and not hacking, and the history of the attack is not the history of pneumonia. On searching further for a cause of the pyrexia, tension and swelling of the gums will be noticed, and the difficulty will be at once explained.

Irritation of the stomach and bowels by acrid secretions or indigestible food is another common cause of irritative fever in children. The intense nervous disturbance excited in young babies by an improper meal induces a rapid rise of temperature, and may culminate in an attack of convulsions. Fæcal accumulation, or the irritation of worms in the bowels, may also, in children and delicate women, produce sufficient disturbance to give rise to fever.

In children the sensitiveness of the system to irritants varies according to the age of the child, according to the natural impressionability of its nervous system, and also according to the state of its general health. Thus, as a rule, the younger the child, the more sensitive is its nervous system; but even in young babies differences will be found in this respect, some being affected much less easily than others by reflex stimuli. In all, however, slow reduction of the strength, such as is produced by progressive chronic disease, gradually reduces nervous sensibility; and a child, enfeebled by an illness of long standing, may show a complete insensibility to all nervous impressions. In young sub-

jects irritative fever, like other forms of pyrexia, is usually remittent; but its remissions are not always found at the same period of the twenty-four hours. There is not, for instance, always a fall of temperature in the morning and a rise at night. One of the peculiarities of this form of febrile disturbance is the irregularity of the fever. A high morning temperature in a young child should always suggest a reflex cause for the pyrexia.

TREATMENT.—The treatment of irritative fever must be directed to the relief or to the removal of the irritating source from which the fever proceeds. The use of febrifuge remedies may be also called for, if constitutional symptoms be marked or persistent.

EUSTACE SMITH.

ISCHÆMIA (*ἰσχη*, I restrain, and *αἷμα*, the blood)—Deficiency of blood in a part, short of complete cessation of the circulation: partial anæmia. See CIRCULATION, Disorders of.

ISCHIALGIA (*ἰσχίος*, the haunch, and *ἄλγος*, pain).—A synonym for sciatica. See SCIATICA.

ISCHL, in the *Salzkammergut*, Austria. A sheltered, bracing, mild, rather moist climate. Altitude 1,560 feet. Thermal common saline baths. See CLIMATE, Treatment of Disease by, and MINERAL WATERS.

ISCHURIA (*ἰσχυρ*, I restrain, and *οὐρ*, the urine).—This word properly signifies the arrest of the secretion of urine (see URINE, Suppression of). It is also applied to mere retention of urine.

ISSUES. See COUNTER-IRRITATION.

ITALY. See CLIMATE, Treatment of Disease by, and NAPLES, PISA, ROME, and SAN REMO.

ITCHE. A popular name for scabies. See SCABIES.

ITCHING. See PRURITUS.

-ITIS. A terminal syllable used to indicate an inflammatory disease of a tissue, or organ; see example, Pleuritis, Hepatitis, or Cystitis.

J

JACTATION, or JACTITATION (*jactatio*, a tossing about of the body, or marked restlessness)—This is a condition mostly associated with certain severe febrile diseases, but also with some nervous affections, with severe pericarditis, or as a sequence of copious uterine or other hemorrhages. A restlessness amounting to jactation may likewise be met with in some patients, when suffering from severe or long-continued pain. It must not be confounded with certain forms of chorea, in which a somewhat similar tossing about of the body may be encountered. The absence of pain and of marked

febrile disturbance, together with the history of the patient, will, even in the cases where the general resemblance is closest, speedily enable the latter condition to be recognised.

JAUNDICE.—SYNON.: Icterus; *Morbus regius*; *Morbus argenteus* (Celsus); *Fr. Ictère*; *Jannus*; *Ger. Gelbsucht*.

DEFINITION.—Jaundice may be defined as a yellowness of the integuments and conjunctivæ, and of the tissues and secretions generally, from impregnation with bile-pigment.

ÆTIOLOGY AND PATHOLOGY.—All cases of

jaundice may be referred to one of two tissues:—

1. Cases in which there is a mechanical impediment to the flow of bile into the duodenum, and where the bile is in consequence retained in the biliary passages, and thence absorbed into the blood.

2. Cases in which there is no impediment to the flow of bile from the liver into the bowel.

These two forms of jaundice have long been recognised; but there is much difference of opinion as to the mode of production of the jaundice in the second class of cases, although these are, perhaps, the most common in practice.

When there is any obstruction to the flow of bile through the hepatic or common duct, the way in which jaundice arises is sufficiently clear. The bile-ducts and the gall-bladder become distended with bile, which is absorbed into the blood by the lymphatics and the veins. If the hepatic duct of a dog be ligatured, and the animal killed after two hours, the lymphatics in the walls of the bile-ducts are seen to be distended with yellow fluid, the fluid in the thoracic duct is also yellow, and so likewise are the intervening lymphatic glands. In patients also who die of obstruction of the bile-duct, the lymphatics of the liver are often found to contain bile. On the other hand, two hours after ligature of the common duct, the serum of blood taken from the hepatic vein contains much more bile-pigment than that of blood taken from the jugular vein, which shows that in cases of obstruction of the bile-duct, bile is also directly absorbed by the veins.

But in a large proportion of cases there is no mechanical impediment to the escape of bile from the liver, and then an explanation of the jaundice is less obvious. Boerhaave and Morgagni long ago suggested that the jaundice in these cases was the result of a *suspended secretion*. They taught that the function of the liver was merely to separate the elements of bile which were already formed in the blood, and that when anything interfered with the function of the liver, the elements of bile accumulated in the blood, and the result was jaundice of the skin and other tissues. Although this view has been strenuously opposed by several excellent authorities, it is, in this country at all events, still generally accepted. It is advocated, for example, by Dr. George Budd, in his valuable treatise on diseases of the liver, although it is but right to add that Dr. Budd makes a special exception with regard to the biliary acids. 'The most skillful chemists,' he says, 'who have recently analysed the portal blood, have failed to detect the biliary acids in it, and have come to the conclusion that these at least are formed in the liver.' This opinion, that the liver manufactures the bile-acids, while it merely excretes the bile-pigment, was adopted by Dr. G. Harley, in his essay on jaundice.

There are, however, weighty objections to this view, some of which may be mentioned.

1. Although bile-pigment appears to be derived from the colouring matter of the blood, it has not yet been satisfactorily shown that bile-pigment, as such, exists ready formed in the blood of persons who have not jaundice. Frerichs denies that it ever has. Lehmann, who has in-

vestigated with great care the changes which the blood undergoes in passing through the liver, has never been able to detect the colouring matter of bile in portal blood, and infers that this, as well as the bile-acids, must be formed in the liver itself. The blood of the hepatic artery has been examined with a like result. It is obvious that if bile-pigment exists in healthy blood at all, its quantity must be very minute, and when we consider that the quantity of bile secreted by the human liver daily is about two pints, and yet that jaundice is not a normal condition, it seems impossible that all the bile-pigment secreted by the liver can be formed in the blood, and it is not probable that part is formed in the blood and part in the liver. The discovery by a few observers of a small quantity of bile-pigment in what appeared normal blood does not prove that it was formed in the blood. It is quite conceivable that it may have been formed in the liver, and have become subsequently absorbed.

2. The secreting tissue of the liver is often for the most part or entirely destroyed, so that bile is no longer secreted, and yet no jaundice results. If bile-pigment be formed in the circulating blood, it is difficult to explain what becomes of it in these cases.

3. If the constituents of bile are formed in the blood, intense jaundice ought at once to follow the extirpation of the liver in any of the lower animals, in like manner as uræa accumulates in the blood after removal of the kidneys. But Muller, Kunde, Lehmann, and Molschoff have repeatedly extirpated the liver of frogs, and have invariably failed to find a trace of the biliary acids, or of bile-pigment, in the blood, the urine, or the muscular tissue.

These and other considerations make it very doubtful if any case of jaundice can with propriety be attributed to a suppression of the hepatic functions; and it is therefore necessary to seek for some other explanation of those cases of jaundice in which there is no obstruction in the bile-duct.

A solution of the difficulty has been proposed by Professor Frerichs, of Berlin. According to this distinguished observer, a large proportion of the colourless bile-acids found in the liver is either directly taken up by the blood in the hepatic vein, or is absorbed from the bowel. Under ordinary circumstances, these bile-acids become oxydised and assist in forming the large quantity of taurin found in healthy lung, and the pigments voided in the urine. But if these normal metamorphoses are interrupted by nervous agencies, or by poisons in the blood, the bile-acids, not being sufficiently oxydised, are converted into bile-pigment in the blood, and the result is jaundice. This view has been supported by two experiments intended to show:—first, that bile-pigment can be produced artificially from the bile-acids, by the action of concentrated sulphuric acid; and, secondly, that colourless biliary acids, when injected into the veins of dogs, are converted in the blood of these animals into bile-pigment. There is, however, far from being unanimity among different observers as to the results of these experiments; and a decision of the points at issue does not appear

to be of material importance for explaining those cases of jaundice in which there is no obstruction of the bile-duct, inasmuch as there are good grounds for believing that not only in jaundice, but in health, a portion of the bile-pigment, as well as of the bile-acids, formed in the liver, is absorbed into the blood.

Although the amount of bile secreted daily must vary in different persons, and in the same person under different circumstances, being modified by the quantity and quality of the food, the activity of respiration, and other conditions, there can be little doubt that but a small portion of that which is ordinarily secreted is discharged from the bowel. Observations on the lower animals and on man himself have shown that the quantity of bile secreted by the liver of a healthy adult averages forty ounces. It is generally admitted that the feces contain but a fraction of the bile-acids (altera) corresponding to this quantity of bile, and it seems equally clear that much of the bile-pigment must also disappear in the bowel. There are grounds for believing that the bile-pigment which so disappears goes to form urinary pigment; while the fact familiar to all clinical observers, that the bile-pigment discharged from the bowel is greatly increased by calomel and other purgatives, without any corresponding increase of secretion of bile by the liver, seems to show that under ordinary circumstances much of the bile-pigment secreted by the liver is not discharged with the feces. It may be added that in carnivorous animals and in snakes, although bile-pigment is secreted in abundance by the liver, the quantity discharged with the feces is even relatively less than in man.

The question as to what becomes of the bile which is not discharged from the bowel has an important bearing on the pathology of the cases of jaundice now under consideration. A large proportion of it is again absorbed, either by the biliary passages, or by the mucous membrane of the bowel. From what is now known of the diffusibility of fluids through animal membranes, it is impossible to conceive bile long in contact with the lining membrane of the gall-bladder, bile-ducts, and intestine, without a large portion of it passing into the circulating blood. The constant secretion and reabsorption of bile is, in fact, merely part of that osmotic circulation constantly taking place between the fluid contents of the bowel and the blood, the existence of which is too little heeded in our pathological speculations and in therapeutics. The quantity of fluid which is being thus constantly poured out from the gastric and intestinal glands, the liver, pancreas, &c., and then reabsorbed is enormous; in twenty-four hours it probably far exceeds the whole amount of blood and fluid in the body. The effect of this continual outpouring is supposed to be to aid metamorphosis; the same substance, more or less changed, seems to be thrown out and reabsorbed until it is adapted for the repair of tissue or becomes effete. How many times this cycle of movement is repeated, before the bile is extruded from the system, we have no means of knowing; but in the course of this osmotic circulation, much of the bile appears to become transformed into products which are

eliminated by the lungs and kidneys, while at the same time this circulation assists in the assimilation of the nutritive materials derived from the food.

Here, then, we have an explanation of those cases of jaundice where there is no impediment to the flow of bile from the liver. Under normal conditions, the whole of the bile that is absorbed is at once transformed, so that neither bile-acids nor bile-pigment can be discovered in the blood or in the urine, and there is no jaundice. But in certain morbid states, the absorbed bile does not undergo the normal metamorphoses; it circulates in the blood and stains the skin and other tissues, and in this way we have jaundice without any obstruction of the bile-duct. The morbid states which, so far as we know, conduce mainly to this result are, for the most part, precisely those in which we might expect abnormal blood-metamorphoses, namely:—

1. Certain poisons, such as those of yellow fever, relapsing fever, pyæmia, and more rarely those of remittent fever, typhus, and scarlatina, also snake-poison, chloroform, &c.

2. Nervous influences, such as a sudden fright, violent rage, great or protracted anxiety, and concussion of the brain.

3. A deficient supply of oxygen, as happens in certain cases of pneumonia, or in persons living in confined and crowded dwellings.

4. An excessive secretion of bile, especially when conjoined with constipation. In this case, unless the bile be removed by purging, the quantity absorbed may be too great to undergo the normal metamorphoses, and the presence in the blood of the untransformed bile causes jaundice.

According to this view, the only pathological difference between jaundices from obstruction and jaundice independent of obstruction of the common bile-duct is that, in the former case, little or none of the bile secreted by the liver can escape from the body with the feces, and consequently all that is secreted is absorbed into the blood, and the quantity thus absorbed is far too great to undergo the normal metamorphoses, while, in the latter case, bile passes into, and is discharged from the bowel, as usual, but that which is absorbed, which in quantity may not exceed what is absorbed in health, remains unchanged in the blood. As might be expected, the jaundice in the former case is usually much more intense than in the latter, although, when an obstruction of the bile-duct has lasted long, the jaundice often becomes paler, not from any diminution of the obstruction, but from the secreting tissue of the liver becoming destroyed, and comparatively little bile being secreted; while in cases where there is no obstruction of the bile-duct, the intensity of the jaundice will vary according to the amount of bile which is absorbed, and the degree of derangement of the blood-metamorphosis.

With these preliminary remarks on the pathology of jaundice, we may now proceed to enumerate its different causes, which may be classified according to the following tabular form:—

1. Jaundice from Mechanical Obstruction of the Bile-duct.

I. Obstruction by foreign bodies within the duct.

1. Gall-stones and inspissated bile.
2. Hydatids and distomata.
3. Foreign bodies from the intestines.

II. Obstruction by inflammatory tumefaction of the duodenum, or of the lining membrane of the duct, with exudation into its interior.

III. Obstruction by stricture or obliteration of the duct.

1. Congenital deficiency of the duct.
2. Stricture from perihepatitis.
3. Closure of orifice of duct in consequence of an ulcer in the duodenum.
4. Stricture from cicatrization of ulcers in the bile-ducts.
5. Spasmodic stricture.

IV. Obstruction by tumours closing the orifice of the duct, or growing in its interior.

V. Obstruction by pressure on the duct from without, by:—

1. Tumours projecting from the liver itself.
2. Enlarged glands in the fissure of the liver.
3. Tumour of the stomach.
4. Tumour of duodenum or pancreas.
5. Tumour of the kidney.
6. Post-peritoneal, or omental tumour.
7. An abdominal aneurism.
8. Accumulation of feces in the bowels.
9. A pregnant uterus.
10. Ovarian and uterine tumours.

B. Jaundice independent of Mechanical Obstruction of the Bile-duct.

1. Poisons in the blood interfering with the normal metamorphosis of bile.

1. The poisons of the various specific fevers.
- a. Yellow fever b. Remittent and intermittent fevers. c. Relapsing fever. d. Typhus. e. Enteric fever. f. Scarletina. g. Epidemic Jaundice.

2. Animal poisons. a. Pyæmia. b. Snake-poison.

3. Mineral poisons. a. Phosphorus. b. Mercury. c. Copper. d. Antimony.

4. Chloroform and ether.

5. Acute atrophy of the liver?

II. Impaired or deranged innervation interfering with the normal metamorphosis of bile.

1. Severe mental emotions, fright, anxiety, &c.

2. Concussion of the brain.

III. Deficient oxygenation of the blood, interfering with the normal metamorphosis of bile.

IV. Excessive secretion of bile, more of which is absorbed than can undergo the normal metamorphosis.

1. Congestion of the liver. a. Mechanical. b. Active. c. Passive.

V. Undue absorption of bile into the blood, from habitual or protracted constipation.

SYMPTOMS.—From what has been stated in the preceding section, it is obvious that jaundice is not a disease, but is a symptom of many different diseases. This view of the matter cannot be too strongly impressed upon the student and practitioner, whose efforts must in every case be directed to discover the fundamental malady. There are, however, certain phenomena connected with jaundice, independent of its cause, which deserve to be mentioned.

1. Intensity of the jaundice. Next to the

liver itself, the skin is the tissue of the body which becomes most deeply jaundiced; but before it becomes affected a yellow tinge is usually observed in the conjunctivæ. There must be a certain concentration of bile-pigment to produce a yellow colour of the skin; in the slightest and more temporary cases, the conjunctivæ only may be affected. Although after ligation of the common bile-duct in the lower animals it has been sometimes found that even the conjunctivæ do not become jaundiced for two or three days; in the human subject jaundice of both skin and conjunctivæ is usually observed within twenty-four hours of closure of the duct.

The colour of the skin varies from a pale sulphur or lemon-yellow, through a citron yellow, to a deep olive or bronzed hue. The tint varies according to the cause and its duration. When the cause is obstruction of the bile-duct, it is light at first, and increases in depth the longer the disease lasts; although in advanced cases, as already stated, the colour sometimes becomes paler, not from the obstruction yielding, but from the tissue of the liver becoming destroyed, and very little bile being secreted. In jaundice from obstruction also, the depth of tint often varies from day to day, not from any variation in the degree of obstruction, but according to the amount of bile secreted by the liver, and the eliminative activity of the kidneys. It is well to remember that what is called 'black jaundice' may result from any cause of obstruction—from gall-stone as well as from cancer. In these cases the greenish or almost black hue is due to the absorbed bile-pigment being vitiated and dark, or to the væscæ being also darkened from imperfect arterialization of the blood, the dark colour resulting from a mingling of the lividity with the colour of bile. When the jaundice is independent of obstruction to the flow of bile, the colour is rarely very deep, and yet these are often the most serious cases. The colour also varies with the age, the natural complexion, and the amount of fat in the individual. It is deeper in the old, the wrinkled, and the dark-complexioned than in young persons of fair complexion, and with plenty of fat. Lastly, it is important to remember that the colour often remains in the skin for some time after the cause of the jaundice has been removed, and that then its departure may be expedited by diaphoretics and warm baths.

2. The *secretions* are tinged with bile-pigment, but some much more so than others. This is notably the case with the urine, by which the greater part of the bile-pigment is eliminated from the body, and which acquires a saffron-yellow, greenish-brown, or brownish-black hue, according to the amount of pigment which it contains. The urine usually becomes yellow before the skin, or even the conjunctivæ; and when the cause of the jaundice is transient, it may happen that the whole of the pigment is eliminated by the urine, without any jaundice appearing in the skin. On the other hand, when once the skin has become yellow, it may remain so for some time after bile-pigment has quite or nearly disappeared from the urine.

Other secretions may contain bile-pigment as well as the urine. The cutaneous glands some-

times eliminate it in such quantity as to stain the linen yellow, but the amount discharged in this way is never great. Instances have been recorded where the secretion of the mammary glands has been tinged with bile-pigment, but they are not very common. Still rarer instances have been noticed where the saliva or the tears have been tinged. It is not a little remarkable that bile-pigment is not eliminated in cases of jaundice by the mucous membrane of the respiratory passages, or of the digestive tube. This is a matter of some practical importance, for, were it otherwise, the stools might contain bile-pigment even when there was complete obstruction of the gall-duct. Still, when either of these mucous membranes is inflamed, and throws off an albuminous or fibrinous exudation, the altered secretions may contain bile-pigment. Thus, when pneumonia coexists with jaundice, there is often bile-pigment in the sputa, which may be distinguished by the nitric-acid test from the greenish or yellow colour often presented by pneumonic sputa, owing to changes in the blood-pigment independent of bile. Indeed, in cases of jaundice bile-pigment may be detected in inflammatory exudations, as in the serum of a blister, before it appears in either the skin or even in the urine. It is probable that those rare cases where the saliva has been noticed to be yellow admit of a similar explanation; in many of them there has been mercurial salivation, a condition in which the saliva is not normal, but contains much albumen.

3. A *bitter taste* is not unfrequently complained of by persons who are the subjects of jaundice. It may denote the presence in the blood of the biliary acids, for taurocholic acid is intensely bitter. It is at all events not due to bile-pigments, which are tasteless. Moreover it is a common symptom in biliary derangements where there is no jaundice.

4. *Derangements of digestion*, such as flatulence, constipation, and an altered character of the motions, may be due to the absence of bile from the motions. Bile is an antiseptic, and when it is absent the intestinal contents undergo fermentation, gases accumulate in the bowels, the motions become putrid, and from the absence of bile they present a pale-drab or clay colour. Bile is also the natural stimulant of the peristaltic action of the gut, and consequently when the supply is cut off, the bowels are usually constipated; but in some cases the putrid fæces act as an irritant and excite diarrhoea. In those cases of jaundice where there is no obstruction of the common bile-duct, the motions may be but little altered.

When bile does not enter the bowel, the digestion of fat is interfered with. Jaundiced patients dislike fat, and do not assimilate it, and the fatty matter in the ingesta may sometimes be detected in the stools. Hence, whatever be the cause of obstruction of the bile-duct, the nutrition of the body suffers: the emaciation may be slow, but it is progressive, until all the fat disappears, and then the weight of the body may remain stationary for many months. With the emaciation there is always more or less muscular debility.

5. *Pruritus*, without any eruption, is a very obstinate and distressing symptom in many cases

of jaundice. It is usually worse at night, and by preventing sleep, may wear out the patient. It is chiefly observed in cases of jaundice due to obstruction of the bile-duct. It is not due to the presence of bile-pigment in the blood, for in some cases it precedes the jaundice, and in others it comes and goes during the persistence of the jaundice. Moreover, in many cases of jaundice it is absent throughout, while it is not uncommon in biliary derangements where there is no jaundice.

6. *Cutaneous eruptions*. Urticaria, lichen, boils, or carbuncles are occasionally observed in connection with jaundice; and likewise that remarkable affection of the skin known as *Xanthelasma* or *Vitiligoidea*, the more severe forms of which are in fact almost invariably associated with persistent jaundice.

7. The *temperature* is not altered in jaundice, except when this occurs as a complication of some acute febrile disease, or when there is inflammatory action in the liver itself.

8. *Slowness of pulse*. A common result of non-febrile jaundice is retardation of the heart's action, and diminution of arterial tension. The pulse may fall to 50, 40, or even 20, and sometimes it is also irregular. This slowness of pulse is particularly noticeable when the patient is recumbent. When there has been antecedent pyrexia, the pulse usually falls on the super-venition of jaundice. Slowness and irregularity of the pulse are chiefly observed in jaundice from obstruction of the bile-duct, and particularly in those common cases known as catarrhal jaundice, and accordingly they are not unfavourable symptoms, as might have been supposed. So far as the writer's experience goes, patients with this symptom invariably recover. It has not yet been explained why this condition of circulation should be present in some cases of jaundice, and absent in others. The natural explanation would be that it is due to some ingredient of the bile, which does not exist in the blood in all cases of jaundice. Some experiments of Röhrig have shown that the biliary acid salts paralyse the heart, and retard its action, while bile-pigment has no such effect. Slowness of the pulse, therefore, in jaundice may indicate the presence in the blood of unchanged biliary acids; but so far there are no observations to show that bile-acids are present in the urine in these more than in other cases of jaundice.

9. *Hæmorrhages*.—In many cases of jaundice the blood seems to become impoverished, by a diminution in the proportion of red corpuscles and fibrine; and hæmorrhages take place from the various mucous membranes, and into the substance of the skin. This hæmorrhagic tendency is particularly observed in conjunction with cerebral symptoms in cases of jaundice, where there is no obstruction of the bile-duct, but it also occurs in cases of mechanical jaundice of long standing, from any cause, when the secreting tissue of the liver has in a great measure disappeared.

10. *Xanthopsia* or *Yellow Vision*.—In rare cases of jaundice, all white objects appear to the patient yellow. The administration of *cantharin* internally has also sometimes been followed by yellow vision, which has ceased as soon as the

colouring matter has been eliminated by the kidneys. This fact, as well as the observation that in several cases of jaundice, with xanthopsy, the conjunctival vessels have been preternaturally distended with blood, has led to the belief that the symptom is due to a tinging with bile-pigment of the humours of the eye. On the other hand, the circumstances that the xanthopsy may intermit, without any change in the jaundice; that it is usually absent when there is intense jaundice of the cornea and other tissues of the eye; and the statement that it may occur in typhus fever and in certain derangements of vision, such as night-blindness, when there is no jaundice, have led some authorities to regard it as a purely nervous symptom.

11. *Cerebral symptoms, and the Typhoid state.* Patients with jaundice are often irritable in their temper and hypochondriacal; and occasionally they are attacked with acute delirium, stupor, coma, convulsions, muscular tremors, tumultus, carphology, paralysis of the sphincters, a dry and brown tongue, and other indications of the typhoid state. These symptoms are most common in cases where there is no obstruction of the ducts, but they also occur in cases of obstruction, usually of long standing, where all or the greater part of the secreting tissue of the liver has been destroyed. Different opinions are held as to their cause. After death no lesion is found of the brain or its membranes, and they are, therefore, most probably due to some alteration of the blood. They are commonly attributed to poisoning of the blood with bile, either from suppression or re-absorption of the secretion. But the assumption that the elements of the bile are preformed in the blood has been already shown to be probably erroneous; and there is equally little evidence that bile is possessed of poisonous qualities, or that its presence in the blood, even to saturation, will give rise to cerebral symptoms. Many experiments have been performed on animals to show that bile is a deadly poison; but there is reason for believing that the bad results observed have been due to the injection into the areolar tissue of decomposing mucus contained in the bile. Bile, from which the mucus has been removed, has been repeatedly injected by Frerichs and other observers into the large veins of dogs, without cerebral symptoms or any bad results ensuing, except that death has in some instances been caused by the entrance of air into the veins. But it is scarcely necessary to turn to experimental enquiries on the lower animals for evidence on the matter, and in all these experiments there are sources of fallacy. There is ample proof that the blood of the human subject may be saturated with bile for months, or even years, without any cerebral symptoms resulting. Dr. Austin Flint, jun., is of opinion that the cerebral symptoms of jaundice are due to the retention of cholesterine in the blood, or to what he has designated *Cholesteramia*. Cholesterine is one of the constituents of bile, and Dr. Flint regards it as an excrementitious product of nervous tissue, the elimination of which from the body is one of the functions of the liver, and the retention of which in the blood he believes to act as a poison like urea. But if the non-excretion of

all the elements of bile does not give rise to cerebral symptoms, it is difficult to understand how they can result from the retention of cholesterine alone. In cases, for instance, of permanent closure of the bile-duct, cholesterine is not discharged from the liver into the bowel, nor does it accumulate in the biliary passages, and yet, if it be retained in the blood, cerebral symptoms rarely occur.

The cerebral symptoms in jaundice are often most severe when the jaundice is slight, and they may occur in diseases of the liver when there is no jaundice. They are best explained by the knowledge which we now possess of the function performed by the liver in disintegrating albuminous matter into less complex substances, such as urea and uric acid, which are eliminated by the kidneys. When this function of the liver is arrested or seriously impaired, urea is no longer eliminated in sufficient quantity by the kidneys; lithic acid and deleterious products of disintegrating albumen even less oxydised, such as leucin and tyrosin, and perhaps others with which we are as yet imperfectly acquainted, accumulate in the blood and tissues; the result is the development of symptoms of blood-poisoning similar to those which arise when the kidneys are unable to eliminate the products of albumen-disintegration, owing to disease of their own structure, or to an excessive formation of urea and other products, as happens in many febrile diseases. In acute atrophy, for example, the structure of the liver is destroyed, and its functions are arrested; leucin and tyrosin take the place of urea in the urine, and are also found in large quantity in the liver, spleen, and kidneys; while cerebral symptoms and the typhoid state are prominent features of the disease.

DIAGNOSIS.—There is rarely much difficulty in the diagnosis of jaundice, but it is well to remember that certain conditions are sometimes mistaken for it, such as chlorosis; the anæmic aspect resulting from organic visceral disease (and particularly from contracted kidneys), from cancer, from exposure to malaria, from Addison's disease, or from lead-poisoning; an undue amount of sub-conjunctival fat; or an unusually dark colour of the ordinary urinary pigment, or the presence in the urine of abnormal pigments, such as those of saffron, turmeric, rhubarb, &c. In every case where there is the slightest doubt, it will be removed by resorting to the nitric acid test for bile-pigment in the urine. If this gives no result, the case is not one of jaundice.

But it is a more difficult matter to determine the cause of the jaundice, and yet this should invariably be the aim of the medical attendant, before forming a prognosis or proceeding to treatment. The scope of this article does not permit a lengthened analysis of the characters distinguishing the different forms of jaundice according to its cause, but the following remarks may be of some service.

1. In the first place it is always well to determine whether or not the jaundice be due to obstruction of the bile-duct. According to Dr. G. Harley this can be done by determining the presence or absence of bile-acids in the urine. Adopting the view that bile-acids are formed by the liver, while bile-pigment is preformed in the blood,

he contends that in jaundice from 'suppression' (or independent of obstruction) the liver does not secrete bile, and consequently no bile-acids being formed, none can enter the circulation or be detected in the urine; whereas in jaundice from obstruction, bile is secreted and absorbed into the blood, and a portion of the bile-acids not transformed in the circulation appears in the urine. But in addition to the strong improbability already urged that any form of jaundice is due to a *suppressed secretion* of bile, clinical experience is entirely opposed to the practical value of the test in question for throwing light on the cause of jaundice. Bile-acids have been found in the urine in cases of acute atrophy of the liver, where there is no obstruction of the bile-duct, and in very many cases of mechanical jaundice they are certainly absent. A more reliable indication of obstruction of the common bile-duct is furnished by the stools. When there is no obstruction, the stools almost invariably contain bile; but when the duct is obstructed, they are clay-coloured. The rule is not without exceptions, and there are several sources of fallacy. The jaundice usually persists for some time after the duct has become pervious, and thus bilious motions may co-exist with jaundice which has resulted from obstruction; or, if the motions be thin and watery, they may appear to contain bile from the admixture of jaundiced urine; or, not unfrequently, when the bile-duct is quite impervious, the motions are of a brownish tinge, owing to the presence of altered blood, which may closely resemble dark bile. A tumour corresponding to the region of the gall-bladder will favour the view that jaundice is due to obstruction of the bile-duct. Lastly, jaundice which persists and is yet slight, is most probably independent of obstruction, for jaundice from persistent obstruction speedily becomes intense.

2. It is always important to note the mode of commencement of jaundice. That which appears suddenly in a person whose previous health has been good, is most probably the result of obstruction of the duct by a foreign body, or it has a nervous origin. The former cause will be distinguished by bilious colic, vomiting, and clay-coloured stools. On the other hand jaundice coming on slowly, but ultimately becoming intense with clay-coloured stools, points to pressure on the duct from without, or to a growth in its interior.

3. A history of previous attacks of jaundice of a similar nature is in favour of a catarrhal origin or of gall-stones.

4. Pain in severe paroxysms concurring with jaundice points generally to gall-stones or cancer, more rarely to hydatids, or to an aneurism of the hepatic artery. Cancer is distinguished from gall-stones by there being usually a history of failing health and emaciation before either the pain or the jaundice.

5. Jaundice concurring with enlargement of the liver is most probably due to cancer or cirrhosis; more rarely to pyemic abscesses, or to waxed liver, with large glands in the portal sinuses.

6. Jaundice concurring with ascites points to cancer or cirrhosis. The diagnosis of the latter will usually be assisted by the physiognomy, the

slightness of the jaundice, the previous habits, and a history of alcoholic dyspepsia; while in cancer there are often darting pains, and the jaundice is usually intense.

7. Jaundice concurring with pyrexia is either secondary to some acute febrile disease; or is due to suppurative pyelophlebitis, a suppurating hydatid tumour opening into a bile-duct, or inflammation of the bile-ducts. Temporary pyrexia may also occur during the passage of a gall stone.

8. Cerebral symptoms associated with jaundice suggest acute atrophy of the liver, poisoning by phosphorus, some specific fever, pneumonia, or nervous shock.

9. Jaundice in a young person, preceded by symptoms of gastric catarrh, is most probably catarrhal.

TREATMENT.—There is no special treatment for jaundice, in all cases the treatment must have reference to what is believed to be its cause. The appropriate treatment will therefore be discussed under the head of the several diseases which give rise to it. Here it is only necessary to observe, that in all cases of jaundice from obstruction it is important to maintain the action of the kidneys, which are the main channel for the elimination of the bile; while portal congestion is obviated by appropriate purgatives. The part which the bile plays in assisting assimilation of nutriment may to some extent be supplied by ox-gall, and creosote will often check the diarrhoea excited by the putrefying feces. Patients suffering from jaundice ought also to partake sparingly of fatty or saccharine food, or of alcoholic drinks.

JIGGER.—A popular term employed to designate the sand-worm or sand-flea. See **CRIKOK**

JOINTS, Diseases of.—Diseases of the joints are classified according to the structure primarily or chiefly involved. They may commence in the synovial membrane, in the bone, or in the cartilage. Primary disease of the ligaments is rare, and is not clinically demonstrable. No form of joint-disease remains long confined to one tissue, so that when the disease is of some duration it will be found to implicate, more or less, every element of the joint-apparatus. In this article the diseases of joints will first be generally discussed, and the individual diseases will then be considered separately.

ÆTIOLOGY AND PATHOLOGY.—The larger articulations, those in constant use, and more especially the joints of the lower extremity, are the most frequently diseased. Thus the knee is more often the seat of disease than any other joint; the hip-joint comes next in order; and then the ankle and elbow. All kinds of joint-diseases are frequent in children and young persons. The first year of life appears, however, to be nearly exempt from these affections, and during the second year they are comparatively rare, perhaps because movement and risk of injury are at that period at a minimum.

Acute arthritis, however, is occasionally witnessed during the first year of life—during even the first six months. It is unconnected with syphilis or injury; very sudden in its appearance, and rapid in course; dangerous to life; and destructive to the articular ends of the bones by suppurative disorganization. The causes of joint-disease in general are connected either with disordered nutrition, in which case it usually assumes an inflammatory type; or with disordered function. The latter may depend on the former, or be unconnected with it. Again, the cause may be local in its origin, or arise from some constitutional defect. Amongst the exciting causes, injury is by far the most frequent. This being often slight, and not followed by any immediate consequences, the connection is frequently overlooked. A blow, or a fall against the edge of a table or down stairs, may readily bruise the synovial membrane, in such exposed joints as the knee or elbow, without causing any external sign. A slight hemorrhage takes place into the synovial cavity or the sub-synovial areolar tissue, and serous effusion may speedily supervene, in this manner a common variety of acute or traumatic serous synovitis is produced. But although injury is the most fertile cause of joint-disease, the articulations may sustain most severe injury without becoming inflamed. It is rare to find any serious consequences result from dislocation; the joint usually perfectly recovering itself. Penetrating wounds of the joints are always serious injuries, they often occasion acute synovitis, and if septic changes occur, are followed inevitably by suppuration in the articulation, and danger both to the limb and life of the individual. Fractures often implicate the joint-surfaces, and prove a frequent source of stiff-joint. Plastic synovitis may be thus set up, causing adhesions; or suppuration takes place; or the callus formed for the repair of the fracture may interfere with the joint motion. Gunshot wounds often produce the severest form of inflammation of joints, suppuration being the usual result. When joint-disease follows an injury it is usually confined to one joint; but when joint disease originates from constitutional causes, more than one joint is often affected; or when only one, the constitutional nature of the cause is manifested in diseased conditions present elsewhere, or by traces of inflammation in other joints, due to the same cause. The deposit of tubercle in the synovial membrane and bone is a frequent cause of chronic joint-disease.

Joint-inflammations are of common occurrence in all kinds of fever; and also as sequelae of the exanthemata. The great frequency of polyarticular serous synovitis in acute rheumatism is well known, as also in purpura and hemorrhilia, where it is complicated with blood-extravasations. In pyæmia the joints are frequently the seat of sero-purulent and purulent effusions; as they also occasionally are in scarlatina. Puerperal synovitis is a variety of the pyæmic. In typhus monarticular arthritis is frequently met with, and the hip is the joint oftenest affected. Endocarditis and polyarthritis are very often associated together, and the endocarditis may precede and give rise to

the joint-disorder by embolism. The fact that multiple joint-affections are met with both in pyæmia and in rheumatism suggests a connection, but what its nature may be is not clear. Although in articular rheumatism pus-formation is rare, we sometimes witness joint-suppuration in such cases; whilst pyæmia and metastatic abscess may originate from ulcerative endocarditis. In chronic synovitis, affecting two or more joints, the heart should always be examined, for traces of endocarditis will sometimes be found. In the exanthemata, typhus, and diphtheria, metastases in the shape of joint-inflammations more or less frequently take place. Joint-inflammation is of frequent occurrence in dysentery. With gonorrhoea a form of arthritis is associated which is called 'gonorrhoeal.' Syphilis in the later stages frequently attacks a joint, the knee by preference, syphilitic deposits taking place in the bone or the sub-synovial connective tissue, but synovial effusion is not common. A suppurative inflammation of the ends of the bone is not rare in children the subjects of inherited syphilis. In gout the joint-structures are affected, as a rule the perisynovial tissue becomes inflamed owing to deposits of urates. Similar deposits even occur in cartilages of encrustation. The great toe is most often affected, but the other tarsal, digital, and larger joints are frequently diseased.

Some ill-understood form of vaso-motor or trophic irritation appears to occasion arthritis, in locomotor ataxy. Effusion into the joint is preceded by pain, and the knee and shoulder joints are those generally affected. In some cases of the disease changes similar to those in rheumatoid arthritis have been observed, generally in the knee, shoulder, elbow, or hip. They occur early in the disease, arise suddenly; are often monarticular; and not rarely give rise to dislocation, especially in the shoulder. These characters distinguish the disease from ordinary rheumatoid arthritis. Severe inflammation of the joints of the paralysed limbs has been observed in cases of hemiplegia. The occurrence of joint-disorder, usually synovial inflammation is frequent in chronic disease of the spine; and it also occasionally happens in acute myelitis, in the form of suppurative arthritis. In both cases the knee is most frequently affected.

ANATOMICAL CHARACTERS.—Joint-disease may begin as an inflammation of the synovial membrane, of the bone, or of the cartilage. Fibrous tissue having but slight tendency to inflame, it is improbable that primary disease affecting the ligaments can be otherwise than most exceptional, but these textures very soon become secondarily affected, from their intimate connection with the synovial membrane. The synovial membrane is perhaps more ready to inflame than any other tissue in the body, and in many joints it is much exposed to injury from without, while excessive joint-movement alone is sometimes sufficient to excite synovitis. Primary disease of the bone comes next in order of frequency. Cartilage is least likely to take on primary disease. Each of these tissues, however, becomes speedily affected by disease which has invaded or commenced in the other.

SYMPTOMS AND DIAGNOSIS.—The local symp-

toms of joint-disease have reference to *impairment of function*, and *change in form*; together with *pain*, both local and sympathetic; and certain *physical signs*.

Impaired function.—Usually this is great in proportion to the natural mobility and importance of the joint, and most evident in the extremities. The earliest symptom in hip-joint-disease is a slight limp or halt, whilst in other joints mere stiffness occurs; the full range of movement is simply curtailed, before actual pain or swelling takes place. The position of maximum relaxation, namely, that intermediate between flexion and extension, is commonly assumed by diseased joints. Even in the earliest stages of disease, the interference with movement is often very great, amounting to a sort of vital ankylosis, produced by the action of the muscles, whose tension prevents the joint-surfaces moving upon each other—an effort to avert pain. This form of ankylosis disappears during narcosis. Muscular or vital ankylosis must be distinguished from the rigidity produced by structural changes. Both synovial effusion and peri-synovial infiltration mechanically hinder free joint-movement.

Changes in form.—Changes in form are due to the alterations in shape and texture of the joint-structure, and to effusions within its cavity. These changes may be best appreciated by careful measurements, and a comparison with the opposite joint. No true estimate of the amount of departure from the normal is otherwise possible. The practitioner is thus better able to diagnose the special character of the swelling, whether it be due to synovial effusion, and confined to the limits of the capsule, causing it to bulge at the least protected parts; or to chronic thickening of the synovial membrane, recognised on palpation by its elasticity and general diffusion; or to disease of the bone and periosteum, when the swelling is deep-seated and hard. By accurate comparison a fluid collection outside the joint, either an abscess or a bursal tumour, may be distinguished from intra-articular swelling.

Pain.—The character of the pain is an important symptom in diseases of the joints. In acute synovitis it is severe and lancinating. In bone-inflammation it is a dull aching pain, with marked local tenderness, liable to periodic exacerbations of an intense kind. Often the pain is of a shooting, starting character, wakening the sufferer from sleep. The pain is of this character and most severe in subarticular otitis. Pyæmic suppuration and chronic synovitis are generally painless.

Physical signs.—When one hand is laid flat upon a diseased joint while the other moves it, certain sensations or sounds are often distinguishable. A peculiar soft crepitation due to the presence of blood-clot, must not be mistaken for the rougher sensations which adhesions afford, the friction-sounds of movable joint-bodies, or the grating of exposed bone. The rubbing of one granulation-surface upon another may be likened to that of two pieces of velvet. Abnormal movements, such as lateral motion in a ginglymoid joint, usually imply extensive joint-disorder. Displacement or partial dislocation, and altera-

tion in form of the joint-surfaces occur as the disease progresses. A notable increase of local heat may be felt in all inflamed joints. When fistulous tracks exist around a diseased joint, they do not often afford direct evidence on being probed of the condition of the joint, but they generally prove the existence of articular suppuration, and disease of the bone.

With respect to the general symptoms of diseases of the joints, it need only be said here that the amount of pain or constitutional disturbance in acute cases varies according to the extent and acuteness of the disease, and the presence and amount of suppuration. In chronic disorders the associated constitutional condition should be investigated.

COMPLICATIONS AND SEQUELÆ.—The complications which occur in joint-disease are generally connected with long-continued suppuration. Amyloid degeneration of the viscera is pretty certain to be present when suppuration has existed for a year or more in young people; less certainly in adults. Hectic fever, tuberculosis, or pyæmia may occur at any period. In the absence or failure of treatment, the patient, should he survive, will suffer from contraction, deformity, and imperfect growth of the limb, together with more or less complete loss of function.

Prognosis.—The prognosis in diseases of the joints will depend on many circumstances, and must be considered both as regards life and as regards function. First, with respect to *life*, the gravity of joint-diseases increases with the size of the joint affected. They are more serious in the lower than in the upper limb. Pyæmia is comparatively rare in acute joint-suppurations—why, it is impossible to say. When pus escapes from the interior of a joint into the surrounding tissues, pyæmia may occur. A continuous high temperature, or a large evening increase associated with hectic, are bad signs; the exhaustion, which depends on profuse suppuration with its attendant hectic fever, amyloid degeneration, and tuberculosis, being the most frequent causes of death in joint-disease. The prognosis as regards *function* is often difficult to determine. After an attack of simple acute or subacute serous synovitis, recovery is generally complete. Joint-function is usually completely lost after suppuration of traumatic origin, recovery being quite exceptional. When the suppuration is of a pyæmic nature, and the patient survives, the effusion may become absorbed, and the joint-motion be preserved. Chronic synovitis with thickening of the sub-synovial tissue, due to infiltration with granulation-material, can seldom be cured except by operation, especially after suppuration has taken place. If recovery should ensue, the joint-function is lost, and deformity is always present. Increased mobility—'lax joint'—is a very rare sequence of joint-disease. It is occasionally seen in the shoulder, and also in the knee.

TREATMENT.—The treatment of diseases of the joints must be directed to preserve the life of the individual; and, as far as possible, the functions of the limb. Of the first and greatest importance among remedial measures is *rest*, which is best secured by fixation of the joint and limb in an appropriate apparatus. This is of cardinal importance to a diseased articulation, just as

motion is a necessity for a healthy one. Immobilisation should not be continued longer than necessary; it will sometimes seriously damage even a previously healthy joint, immobilised on account of fracture of the limb; and a continuance of rest after all diseased action has subsided often exerts a very prejudicial influence. Rest, however, should be continued so long as pain and increased temperature persist.

Position.—The same means adopted to secure immobility must be utilised to obtain the best available position for the future function of the part, should ankylosis become inevitable. In the ankle the foot should be maintained at a right angle; the hip and knee must be extended in the axis of the body, the elbow is generally flexed to a right angle, the position in which the limb is most useful. Splints of various forms are used, and we possess in plaster-of-Paris and starch ready and invaluable means of producing an apparatus, which gives uniform and equable support of a simple and very perfect kind.

Extension exerts a beneficial influence, as well by immobilising the joint, as by its power to remove contraction and deformity. It relieves pain and abates the symptoms rather by keeping the joint at rest, and changing the surfaces of contact, than by any actual distraction of the joint-surfaces. A much greater weight than a patient could tolerate must be used before any such separation could occur. Extension often even increases the intra-articular pressure. By straightening the limb it removes the joint from its position of maximum relaxation, and puts the skin and tendons on the flexor aspect on the stretch, and alters the mutual accommodation of the joint-surfaces.

As there is almost invariably an increase of temperature in the affected joint the application of cold, by means of ice-bags or coils of cold water tubing, is indicated. Cold acts most beneficially in all acute, and many subacute inflammations. Even in deep-seated joints like the hip, it will often soothe the pain and abate the symptoms, but it is more applicable to the superficial joints. Cold is both anæsthetic and prophylactic in its action. The sensations of the patient in respect of the continuance of cold applications must be consulted. In most cases they are grateful. In chronic joint-affections when an acute attack supervenes, threatening suppuration, cold should also be applied. Cold applications may in some cases be continued for weeks or months with advantage. When the acute symptoms have passed off, and it is desirable to encourage lymphatic activity and absorption, the cold must be discontinued, and compression, together with friction and warmth, substituted. Cold is not applicable to purely chronic cases without much pain or tenderness.

In some instances of acute and subacute arthritis *local depletion* by means of leeches or scarification is very useful, and this may be combined with hot *fomentations* in cases where cold is not well borne. In chronic inflammation of the bone the *actual cautery* sometimes procures immediate abatement of the pain, and, after a time, the subsidence of the inflammation. The *hyperæsthetic cautery* may be used, or, still better, *lithic* cauterisation, over the most sensitive

points. Or an *issue* may be employed instead.

Compression by strapping, or with a thick layer of cotton-wool and a tightly applied bandage over it, is applicable to the chronic stages of joint-disease. It must be discontinued if it occasion pain. It is better calculated to remove fluid effusions than the plastic material pressed out into the perisynovial tissue. For these cases the more continuous compression of a properly applied elastic bandage will prove more efficient; or the strapping known as 'Scott's dressing.'

Massage is a most valuable local means for the dispersion of chronic swellings of joints. It both removes the results of diseased action in the joint, and helps to restore its function. It is well suited to disperse serous effusions when the acute stage is over; for cases of plastic synovitis it is also useful, but not for cases of the type known as *tumor albus*. It produces a diminution of the sensibility of the part, and a local increase of temperature, and the lymphatics are stimulated to increased activity. There are several modes of employing massage. The first is centripetal stroking with the palm of the hand from the periphery of the affected part towards the centre of the body, called *effluage*, one hand following the other in immediate succession. The amount of pressure varies with the circumstances of the case. This will readily disperse fluid effusions both of blood and serum. Friction-massage is another useful method, and is practised by pressing the palm firmly upon the surface, and then rotating it. This plan may be combined alternately with the last method, massage proper—*petrissage*—which is done by running up the soft parts vertically from the bone with both hands, and compressing them, always in a centripetal direction.

Forcible movements.—Forcible movements, which break-down adhesions, are often most useful in cases of stiff joint arising after protracted immobilisation, after fracture in the vicinity of a joint, or after a severe sprain. Pain will be relieved in this way, and mobility restored in some instances, in a degree quite remarkable.

Constitutional treatment.—Where any general taint exists, this must be treated at the same time. A tendency to tubercle must be met by iron, tonics, good food, and fresh pure air. Gout, syphilis, or rheumatism must, when present as a diathesis, be appropriately treated.

Operative treatment.—Puncture alone, or combined with antiseptic washing-out of the articulation, may often be performed with advantage, to evacuate the fluid in a distended joint, or to diagnose the presence of pus and evacuate it when suppuration has taken place. Sufficiently free incisions, however, and the insertion of drainage tubes are generally to be preferred in cases of joint-suppuration; and with these should be combined the washing-out of the joint-cavity with a three- or five-per-cent. solution of carbolic acid, or other adequate antiseptic. It has been proposed to substitute free incisions and drainage for excision of the joint, in certain chronic forms of disease, such as white-swellings, but excision is probably in most respects preferable. Excision is practised for chronic joint-disease not amenable to other means; it is not a substitute

for amputation, but is intended to obviate its necessity. Subperiosteal resection, where practicable, possesses many advantages, especially in cases of traumatic origin. The attachments of the muscles and tendons, and the cellular inter-spaces between them, are thus left undisturbed. The chances of periarticular suppuration are diminished, and the bleeding is reduced to a minimum. There is more complete bony reproduction of the joint-surfaces, and in young persons a new joint very similar to the normal is in some instances formed, while in all cases there is a probability of better subsequent function and position. The operation thus performed requires time and skill. It is scarcely applicable to the knee or even the hip, and is unsuited for cases of chronic synovial disease, where it is of the last importance to excise all the diseased granulation-material. The after-treatment of excisions is of great importance. Plaster-of-Paris bandages supply one of the most useful means of immobilisation, especially in those cases where ankylosis is sought for, as in the knee; and the splint should be unchanged, if possible, for four or five weeks. In the elbow, shoulder, and wrist, where mobility is the end aimed at, passive movement should be commenced as soon as the condition of the wound admits of it, namely in about a week or ten days. Galvanism must be used at a later period to restore the wasted muscular apparatus.

Amputation is only performed as a last resort. It is very rarely needed for joint-diseases in the upper limb, except perhaps the wrist, when the hand is permanently crippled. In the lower limb, amputation must be performed in those cases in which the patient has lost all strength and healing power, from the drain of a long-continued discharge. It is advisable where amyloid degeneration or incipient tuberculosis exists, or in any case, in short, in which the power of the patient is inadequate to furnish the amount of repair required in the expectant form of treatment, or in case of excision, always a more serious operation than mere amputation. Amputation should also be adopted in those cases in which the local disease, especially of the bone, is too extensive to admit of a good functional result after excision. In the very young excision is very undesirable, since the epiphysis is almost of necessity sacrificed, and the growth of the limb checked. Resection in some joints is practised to avert ankylosis, or to restore the lost function of the joint, as in the shoulder, elbow, and wrist. Various congenital and other deformities of the joints may be removed by osteotomy of the bones concerned.

The chief diseases of joints will now be separately considered in alphabetical order as follows:—1. Cartilages, Diseases of; 2. Congenital Dislocation; 3. Immobility; 4. Inflammation, Acute, of the Synovial Membrane; 5. Inflammation, Chronic, of the same; 6. Gonorrhoeal Inflammation; 7. Gouty Inflammation; 8. Strumous Inflammation; 9. Loose Cartilages in Joints; 10. Nervous Affections; 11. Rheumatic Arthritis, Chronic; 12. Serous Effusions; and 13. Syphilitic Disease. Rheumatism in its several forms will be considered separately.

1. *Joints, Cartilages of. Diseases of.*—Primary chondritis as a form of joint-disease is neither clinically nor pathologically established. The cartilage has little tendency to active inflammation; it is not sensitive to pain; chronic changes take place in it as the result of impaired nutrition, rather than inflammation. The cartilages of encrustation are the residue, which does not ossify, of the mass of fetal cartilage forming the bone-ends. We meet in the joints of the aged with depressions and fibrous scars, caused by partial atrophy of the cartilage; these changes do not occasion symptoms during life, beyond sensations of creaking and roughness in the joint when moved.

Almost all the changes which occur in the articular cartilages are secondary to synovitis and osteitis, and more or less passive. In serous synovitis the cartilage is softened and swollen, and becomes to a certain extent oedematous. In suppurative synovitis it becomes rough, sodden, and yellow: its cells burst, the intercellular substance fibrillates, and portions may necrose. The cartilage-changes in chronic synovitis have been already discussed, and others will be referred to later.

Young growing bones, like the periosteum covering them, readily inflame, and as soon as the inflammation invades the articular surface of the bone, the cartilage becomes loosened and necrosed, or invaded by the granulation-tissue springing from the bone. The cartilage is softened, its capsule bursts; fibrillation occurs; and at different places it becomes thinned. Perforations occur in it, leading to the bone, giving it a sieve-like appearance. Where the inflammatory process is more acute, the whole of the encrusting cartilage may become at once detached from the bone beneath.

In these cases the pain, especially at night, is very severe. Involuntary starting of the limb causes intense suffering, wakening the patient from sleep with a scream. This symptom was formerly considered distinctive of ulceration of cartilage, a process which is wholly painless when it occurs without other disease in the joint, but it is probable the pain is due to pressure upon the inflamed bone, and it will sometimes greatly abate when the cartilage wholly disappears. Disease commencing near the epiphyseal cartilage often extends to the adjacent joint. Those joints in which the epiphyseal junction is within the capsule, as, for instance, the hip, run a double risk from bone-inflammation.

2. *Joints, Congenital Dislocation of.*—*Description.*—This is a curious and ill-understood affection of the joints. It is almost exclusively confined to the female sex. The hip-joint is nearly always the one affected, and the displacement is generally double. It has often been erroneously mistaken for morbus coxae, and treated accordingly.

It probably occurs in early fetal life from defective formation of the joint-surfaces. It is not discovered until the child begins to walk, which it generally only commences to do at a late period. When the hips are affected, the gait is accompanied by a most ungainly swaying of

the body from side to side like the waddling of a duck. All that can be done is to supply a well-contrived artificial support to the pelvis and limbs.

Genu valgum and *genu varum* (knock-knee and bow-knee) are two forms of disabling and unsightly deformity of the lower limbs. They are often due to an abnormal development of the condyles or shaft of the femur, or the tuberosities of the tibia, and to changes of a rickety character at the epiphyseal junction. In extreme cases progression is greatly interfered with. The symptoms are painfully obvious.

TREATMENT.—Treatment of the limb by splints and apparatus and forcible straightening in plaster-of-Paris bandages succeeds in the milder cases, but in those of a severe type, or in persons of ten years or upwards, this plan is most tedious, and is usually attended by complete failure. The subcutaneous division of the internal or external condyle, according to the nature of the deformity, restores the joint-surfaces of the femur to their normal level, and is attended by the happiest results both to the form and function of the limb and joint. It is an easier and in many ways a more successful operation to divide the shaft of the bone with a chisel near its articular extremity, and thus procure the rectification of the limb.

3. Joints, Immobility of.—**SYNON.**: Ankylosis; *Fr. Ankylous*; *Ger. Gelenkverwachsung*.

ÆTIOLOGY.—This condition may be due to changes in the structures of the articulation—*true ankylosis*; or in those surrounding the joint—*false ankylosis*. It may be fibrous and incomplete, or bony and complete. False or spurious ankylosis—extra-articular—may depend on muscular spasm or rigidity, on cicatricial contractions; on paralytic or spasmodic affections; or upon prolonged disease of the joint. It is often difficult, even under chloroform, to distinguish the presence of absolute bony ankylosis, as the fibrous form may be so strong and extensive as almost wholly to prevent movement. The two varieties are but degrees of the same process. Both may result from previous inflammatory changes in the joint, either of the nature of plastic synovitis, or of granulations springing from the bone and other joint-tissues, becoming further organised. Fibro-cartilaginous ankylosis is a common form in young persons. In time it usually becomes converted into true bony ankylosis.

The marked ankylosis which tonic spasm and rigidity of the muscles produce in the early stages of some joint-diseases, as in the hip-joint and knee, may be called *vital or physiological*. It is induced by an effort to avert pain; it disappears entirely during narcosis. A joint may become stiff and ankylosed by long fixation on account of some injury or disease elsewhere, especially if it be retained in a flexed position, as the muscles of the flexor side actually shorten when their points of origin and insertion permanently approach one another. The same thing may also happen in the myogenic affections due to paralysis; in which the cartilages and bones atrophy at the same time.

TREATMENT.—The treatment of disease of

joints should, in all cases where it is possible, be prophylactic against the occurrence of ankylosis. When this has taken place in an incomplete degree, an attempt to restore the function of the limb must be made by breaking down the adhesions by forcible or gradual extension, by passive motion, by massage, and by tenotomy of the tense tendons. Excision is indicated to restore motion in complete ankylosis of such joints as the wrist, the elbow, and the shoulder. In other cases of complete ankylosis, especially in the lower limb, surgical interference should be confined to an attempt to rectify a faulty position either by tenotomy, extension, forcible straightening, excision, or osteotomy. Amputation can only be needed in extreme and otherwise irremediable deformity.

4. Joints, Inflammation, Acute, of the Synovial Membrane of.—**SYNON.**: Acute Synovitis; *Fr. Synovite*, *Ger. Synovitis*.

This is one of the most common of all joint-affections. Probably in half the total number of chronic joint-diseases the synovial membrane is first affected. The synovial membrane is very rich in vessels and cells, and much exposed to injury, and to the effects of joint-movement. An inflammation beginning at one point soon spreads over the whole synovial sac.

DESCRIPTION.—Acute synovitis is a very common result of injury; it also occurs in rheumatism, gout, pyæmia, and other diseases. It may be serous, sero-fibrinous, or purulent. Serous synovitis is the simplest and most common variety. Even a slight external injury is often sufficient to produce it, a sprain of the joint, or even excessive movement, may cause it, as well as the constitutional disorders already mentioned. The knee is very often affected, from its exposed position and the large area of the serous membrane lining it. The synovial membrane becomes injected and thickened, with œdema of the subsynovial tissue. The natural secretion is increased in quantity, and many cells are shed into the joint cavity, the capsule becoming swollen, tense, fluctuating, or elastic. The least protected parts bulge, from the pressure of the effused fluid, and the normal contour of the joint is lost. It is usually semi-flexed. A severe burning, cutting pain is experienced in it. It is exceedingly sensitive to pressure, and painful on the slightest movement. There is usually considerable fever. When the inflammation is more intense, the synovitis becomes sero-fibrinous. Flakes of lymph are mingled with the synovia; layers of false membrane cover the synovial membrane, which is considerably thickened and dull red in colour; and the constitutional disturbance is greater. Finally, it is but a short step from this to suppurative synovitis. If the irritant cause continue its action, the leucocytes filling the meshes of the synovial membrane are shed in larger quantity; the fluid becomes turbid and puriform; the fever and local symptoms increase very much in severity, the external parts become implicated in the inflammation within; and joint-suppuration or abscess is the result.

TREATMENT.—The treatment of the first two stages of synovitis is directed primarily to check

the progress of the inflammation, and then to procure resolution, and absorption of the effused fluid. Fortunately the synovial membrane possesses very active absorbent powers, and early and efficient treatment, conjoined with removal of the source of irritation, will generally ensure a cure, with complete restoration of function. The chief means are cold applications; immobilisation till the acute stage is over, and then compression and friction, or in suitable cases counter-irritation. Gout, rheumatism, or other diathesis, must be appropriately treated at the same time.

In those cases in which the inflammation has persisted for some time, and plastic effusion has taken place on the surface and in the substance of the synovial tissue, the joint will remain for a long time stiff and thickened, and its function impaired, after all acute symptoms have subsided; whilst in those cases where the inflammation has continued long enough to involve the other joint-structures, a perfect cure may not be possible.

When suppuration occurs, the joint must be dealt with as any other abscess-cavity. Free incisions must be made into it, and it should be thoroughly washed out with some antiseptic solution, free subsequent drainage being provided for. In the more favourable cases, ankylosis in a convenient position will be obtained. Recovery of function is very rare. In other cases the suppuration continues; the cartilages of encrustation become necrosed and detached, the bone becomes exposed and carious, and either excision or amputation must be performed to save the patient's life or limb.

5. Joints, Inflammation, Chronic, of the Synovial Membrane of.—SYNOV. Chronic Synovitis.

Chronic synovitis may arise as the sequel of the acute disease; or, as is more frequent, it may depend on some constitutional dyscrasia, or at least some continuously acting irritant, although in the first instance it is generally excited by an accidental injury.

VARIETIES.—There are three chief varieties of this disease which are often co-existent, namely:—*Purulent Synovitis*, *Granulation Synovitis*, and *Papillomatous Synovitis*.

a. *Purulent Synovitis*.—In this variety a delicate membrane will be found, stretching from the inflamed and thickened synovial margins more or less over the surface of the cartilage, to which it may be in whole or in part adherent.

b. *Granulation Synovitis*.—The second, or granulation-form, is a more advanced stage of the disease. In it the synovial membrane is often completely replaced by granulation-material, which encroaches on the margins of the cartilages, and, as the disease progresses, invades them, and coalesces after a time with granulations springing from the inflamed bone. These granulations are pink or greyish-red, not so vascular as those in an ordinary wound. They have little tendency to cicatricial change, and are prone to soften down and form abscesses.

The synovial membrane often becomes enormously thickened from the granulation-material

accumulated in it, and this form of disease is frequently associated with the tuberculous diathesis. Bodies identical with milary tubercles are very often found in the semi-gelatinous or pulpy synovial membrane; the whole constituting what is known as *tumor albus*, or 'white-swelling.'

SYMPTOMS.—The more prominent symptom associated with the form of chronic synovitis just described is the presence of a uniform semi-elastic swelling, caused by the sero-fibrinous infiltration of the synovial membrane. The skin is whitish, tense and smooth, whence the name *tumor albus*. The amount of synovial effusion into the joint is usually limited; the pain is seldom severe; the amount of joint-movement is diminished; and there is usually contraction of the limb, and sometimes partial dislocation. When suppuration occurs, there is more pain and fever. The progress of the disease is generally very chronic, extending over months or years, and allowing the patient at intervals to take moderate exercise. Exacerbations take place, however, from slight causes, or without cause, attacks of subacute or acute inflammation supervene, and sooner or later abscesses form, communicating both with the cavity of the joint, which becomes totally disorganised, and with the surface.

Brodie's 'pulpy disease of the synovial membrane' is simply an exaggerated degree of granulation synovitis, in which the subsynovial tissue becomes enormously thickened by successive attacks of inflammation.

TREATMENT.—The disease is most rebellious to treatment, and scarcely curable amongst the poorer classes without operation. Sometimes the diseased tissue is got rid of by suppuration; and, if the patient's strength suffice, a cure by ankylosis, probably accompanied by considerable deformity, will ensue. Generally, however, the symptoms become worse, the general health gives way from the drain of the continuous discharge, or amyloid or some other intercurrent disease kills the patient. At any time, as in a suppurating wound, pyæmic symptoms or hæmæ may set in.

c. *Papillomatous Synovitis*.—SYNOV.: Fibriated disease of the synovial membrane; Papilloma, or Papillary Fibroma of the synovial membrane; Ger. *Gelenksotten*.

This is a peculiar form of joint-disease dependent on chronic synovitis, in which numerous pedunculated bodies, cylindrical or fusiform, varying in size from a pin's-head to a large pea, project from the membrane, generally near the cartilage margins, or they may cover the entire surface. They are identical in minute structure with the synovial fringes. Some become detached, and fall into the cavity of the joint. The disease is essentially a hyperplasia of the synovial adventitia; and there may be dozens or hundreds of these bodies present in one joint. Occasionally they contain cartilage-cells, or osseous particles. The joints in the lower limb are most often affected.

TREATMENT.—The disease is scarcely remediable except by excision of the joint, which may be practised in those cases in which there is serious loss of function.

6. Joints, Inflammation of, Gonorrhoeal. This disease is often called 'gonorrhoeal rheumatism.' It is almost always observed in the male, very rarely affecting the female. Generally one joint, usually in the lower limb, is involved, as the knee or the ankle. It is not so common in the upper extremity. It may affect several joints in succession. It may occur at any period of a gonorrhoeal or even a gleet discharge, of which the patient himself is possibly unaware. The fibrous tissues of the joint seem to be primarily engaged. Scleritis and inflammation of the internal layer of the cornea often coexist, but never either endo- or pericarditis.

SYMPTOMS.—The joint affected is exquisitely tender on pressure; it is swollen rather from subcutaneous oedema than by intra-articular effusion, which is usually inconsiderable; and one side of the joint is often more affected than the other. The fever is not in proportion to the intensity of the local symptoms, the rise of temperature being slight. The course of the disease is slow and obstinate; but when cured it is not liable to return, except with a fresh attack of gonorrhoea. These characters distinguish it from ordinary rheumatism.

TREATMENT.—Rest, cold applications, and the internal exhibition of iodide of potassium constitute the best treatment for gonorrhoeal inflammation of joint. See RHEUMATISM, Gonorrhoeal.

7. Joints, Inflammation of, Gouty.—Gout frequently occasions synovitis, by the deposit of urate of soda in the perisynovial tissue, which excites a synovial effusion. The attacks are very acute and painful; and as they recur, the joint becomes more and more disorganised, from permanent deposits of urates in the cartilages and bone, as well as in the perisynovial tissue. The use of the joint is lost, and the 'chalk-stone,' as it is called, acting as a foreign body, sometimes produces an abscess, or an ulceration very troublesome to heal. When the collection is quite superficial, it may often be evacuated by incision with great relief. See GOUT.

8. Joints, Inflammation of, Strumous.—Scrofula and tubercle are often associated with joint-diseases. Scrofulous or strumous inflammation of a joint is a vague term, but we are without a better. It is a form of chronic inflammation in ill-nourished persons—nearly always children—who live under bad hygienic conditions, and are prone to deposits of tubercle. It is observed most frequently in the knee- and hip-joints.

ANATOMICAL CHARACTERS.—This disease generally commences in the synovial membrane, which becomes thickened, and by degrees converted into a semi-gelatinous mass of granulation-tissue, yellowish-white or pink in colour, or the disease may originate in osteomyelitis of the end of the bone. After it has existed for some time, it is difficult to determine in what tissue it may have originated, and it is of no clinical importance to do so, for in any case the later stages of the malady present similar features. The cartilages are encroached upon from their margins and from their deep surfaces by the granulations, whilst active changes occur simul-

taneously in their substance, similar to those already described. The ligaments soften, and all the structures of the joint become involved. Frequently small masses of necrosed bone will be found in the cancellated structure, and the granulations have a great tendency to suppurate. In the thickened synovial membrane, and also in the ends of the bones, military nodules, identical with tubercles, may very frequently be detected.

SYMPTOMS.—In strumous inflammation the joint is uniformly swollen, tense, elastic, with a white glistening surface, and enlarged veins shining through the skin. The patient can usually move about until suppuration has taken place, as the pain is never very severe in the intervals of the acute attacks of inflammation which supervene from time to time. Enlargement of the lymphatic glands, or marks of strumous ulceration elsewhere are seldom wanting; whilst sooner or later a large proportion of the individuals affected by this form of joint-disease show signs of general tuberculosis. Sometimes this state precedes, but generally it follows, the local joint-affection. Inherited syphilis appears to be a predisposing cause of strumous arthritis.

TREATMENT.—This must be mainly directed to improving the patient's general condition. A purely local treatment, short of a complete removal of the diseased structures, is not of the least use. When the joint has become disorganised, as before described, excision should be performed before the viscera become implicated. If other organs be involved, or the local disease be too extensive, then amputation becomes imperative. When not relieved, fresh foci of suppuration form; the patient becomes more and more exhausted, or some intercurrent disease sets in. It is rare for spontaneous cure to happen.

9. Joints, Loose Cartilages in.—SYNON.: *Fr. Corps flottans articulaires, Ger. Gelenkmause.*

DESCRIPTION.—'Loose cartilages' in joints may originate either from chronic inflammation, or from traumatic causes. They may be single or multiple. The knee-joint is most frequently affected, and in it the most serious symptoms are produced. These bodies may be fibrous, lipomatous, chondromatous or osteo-chondromatous. They may be produced from polypoid growths springing from the synovial membrane in certain forms of chronic synovitis, and in arthritis deformans; and they are then usually of the fibrous or osteoid variety. Lipomatous free bodies are rare and are derived from the sub-synovial fatty tissue, being produced in a fashion analogous to the appendice of the great intestine.

The chondromatous and osteo-chondromatous are the largest and most important varieties of these bodies, hence the common term 'loose cartilage.' Portions of the joint-surface may sometimes become detached, as the consequence of an injury, by a process of quiet necrosis. They thus become loose in the joint. There is good reason to believe that some of these bodies may obtain nourishment from the surrounding synovial fluid, and that cartilage and even bone can be developed in them subsequently to their detachment.

SYMPTOMS AND DIAGNOSIS.—The symptoms of loose cartilages in a joint vary very much. In some instances these bodies cause no inconvenience. In others they produce repeated attacks of excruciating pain, followed by synovitis, laying the patient up for weeks; whilst in the most severe cases the limb may become almost useless. When the knee is the joint affected, the patient experiences great insecurity in walking, the loose body from time to time becoming wedged between the joint-surfaces. The joint is thus 'locked.' The patient may suddenly fall, or faint with pain, an attack of synovitis follows, and with a frequent repetition of this process joint-disorganisation may finally result. The prognosis as regards function is always bad.

TREATMENT.—The treatment of loose cartilages may be either *palliative* or *radical*. The former method consists in applying support to the joint; limiting its movements, and fixing the loose body in some synovial pouch where it cannot interfere with the articular surfaces.

The *radical* method consists in excising the body—an operation, with few exceptions, almost exclusively practised upon the knee-joint. The body may be removed by a free direct incision into the joint, and squeezing the body through the wound at once. Or the indirect manner of operating may be adopted. This consists in subcutaneously incising the capsule of the joint with a long, narrow-bladed knife introduced at some distance from the articulation; forcing the body through this incision into the cellular tissue outside, and then closing the small external puncture in the skin. Three or four weeks later the 'cartilage' may be removed by a superficial incision, or left undisturbed, when it often becomes absorbed.

In appreciating the comparative value of the two plans, it may be said that the former has hitherto proved more uniformly successful *quoad* extracting the body, but that it has been more dangerous to limb and life—a danger, however, which antiseptic precautions will in future reduce to a minimum. The indirect method has been attended by a considerable number of failures in the extraction of the loose cartilage, especially if it be pedunculated; but it has hitherto proved a much less dangerous operation. The extremity should be immobilised afterwards for two or three weeks.

When some dozens of these bodies are present in a joint, many of them free, many attached, excision of the articulation is often the only remedy. This is a severe measure, and not to be lightly undertaken, in the joints of the lower limb at all events.

10. Joints, Nervous Affections of.—**SYNOM.**: Hysterical joint; Neuralgia of Joints; Arthralgia; Fr. *Arthralgie hystérique*; Ger. *Gelenkneurose*.

DESCRIPTION.—*Hysterical* affections present symptoms simulating real joint-disease so closely, that the strongest therapeutic measures have often been exerted, though in vain, for their cure. Prolonged immobilisation, blistering, the actual cautery, resection, and even amputation, have been practised upon joints in which there was not a trace of organic disease.

The existence of hysterical affections of joints is denied by some, but assuredly they do occur; and most often in young women, well-to-do in life, with disordered catamenia. The same thing occurs, but less frequently, in young men. The disease is not witnessed under the age of puberty. The hip and knee are the joints principally complained of—most frequently the latter. An all-important feature of a hysterical joint is that, while the local symptoms may be intense, the general symptoms are either absent, or in no sort of proportion to the local.

A special character of this disease is that deep pressure is often less painful than superficial pressure, and that the pain and tenderness are vague, shift from one point to another, and will disappear at a given spot when the patient's attention is directed elsewhere. There is pain on movement, but of an indefinite character, and not so limited or localised as in real disease. Nocturnal startings do not occur, the patient may enjoy uninterrupted sleep for hours. There is never a continuous rise of temperature, either general or local; the co-relation of the symptoms is not the usual one, the function of the joint is much more interfered with than the other features of the disease present would appear to justify. There is an exaggerated fear of examination, and the *juices hysterici* is often well-marked. There may be thickening around the joint, and even marked synovial effusion into it, but these conditions are passive in character, and generally due to the treatment employed. The limb is wasted and consequently weak, but never to the same extent as in real joint-disease. Exacerbations occur at the menstrual period. A careful inquiry should be made into the history and antecedents of the case. An examination under chloroform will often afford important evidence, and the patient's symptoms will be improved afterwards by the movements then practised on the joint.

Neuralgic pain in the articulations may arise under different circumstances. It may be the referred pain, unattended by local lesion, which is so frequent in the knee in cases of hip-joint disease. Neuralgic pains in various joints are observed in the preliminary or early stages of chronic myelitis. In the first stage of locomotor ataxia the knee may be affected by severe neuralgia when the disease is low down in the cord; or the shoulders when it is at a higher point. Lastly, so called neuralgia of a joint may really indicate some obscure lesion, as chronic inflammation of the bones entering into the formation of the articulation.

TREATMENT.—The methodical exercise of an hysterical joint is as plainly indicated as rest is imperative in a case of organic disease. The bowels should be regulated, as also the menstrual flow. *Asafoetida*, iron, and quinine are most important remedies; and healthy mental and moral influences are valuable adjuncts. 'Get up and walk' is a good prescription in many such cases. Very careful and repeated examination should always be made, to exclude any possible form of chronic inflammation, before pronouncing a joint to be hysterical. It must not be forgotten, however, that after slight injuries which produce some inflammatory symp-

toms, those of hysterical joint may supervene, and persist long after all traces of organic disease have disappeared.

The treatment of *neuralgia* connected with a joint will necessarily vary with its cause. See *NEURALGIA*.

11. Joints, Rheumatic Arthritis of, Chronic.—*SYNON.*: Osteoarthritis; Fr. *Arthrite avec usure des cartilages*; *Arthritis sèche*; Ger. *Altersackgelenk*.

ÆTIOLOGY AND PATHOLOGY.—The number of names that have been applied to this disease betrays the obscurity enveloping its pathology. In nature it is, however, essentially a senile degeneration, preceded by chronic inflammation; and is, in part, perhaps the result of wear and tear of the joint. It is most common in hard-working people, exposed to the influence of wet and cold, and in the aged. One or many joints may be affected; generally the fingers, the toes, the hip, and the knee. It may be set up by injury, such as a sprain, dislocation, or fracture; or it may arise without known cause. It is difficult to say which tissue is primarily at fault, but sooner or later all become involved. The synovial membrane inflames; papillary outgrowths form upon it; the cartilage swells; and the ends of the bones enlarge. After a time the quantity of synovial fluid diminishes; the joint-friction increases; the cartilages are rubbed away at the surfaces of contact; and afterwards the bone itself, which becomes denser by interstitial deposit, disappears. The surface is eburnated, and marked with striae produced by friction; whilst deposits of new bone, which may often be felt externally, form around the margins of the joints, so that the area of its surfaces becomes greatly increased.

SYMPTOMS.—The symptoms of chronic rheumatic arthritis chiefly consist in constant pain, of a dull aching character, and worse at night. Motion becomes more and more difficult and painful as the disease advances; but ankylosis never occurs. Rough crepitus is felt both by the patient and the surgeon when the joint is moved. See *RHEUMATIC ARTHRITIS*.

TREATMENT.—The treatment of rheumatic arthritis can only be palliative, and consists in the use of warm douches and other warm appli-

cations, and the administration of iodide of potassium internally. The disease is incurable.

12. Joints, Serous Effusion into.—*SYNON.*: *Hydrops articuli*; *Hydarthrosis*; Fr. *Hydarthrose*; Ger. *Gelenkwassersucht*.

This is a form of chronic serous synovitis, in which there are no obvious inflammatory symptoms. The joint sometimes becomes greatly distended, the ligaments are stretched; and in consequence there is a sensation of tension and foolishness in the articulation. The knee and elbow are most frequently attacked; and the disease is often associated with a gouty or rheumatic diathesis, or with rheumatoid arthritis. It is very difficult to cure. The joint may be punctured and the fluid drawn off, or, still better, it may be injected and thoroughly washed out with iodine (equal parts of the compound tincture and water) or a carbolic acid ($\frac{2}{3}$ to 5 per cent.) solution; but relapses are common.

13. Joints, Syphilitic Disease of.—This disease may originate in children, in the form of a suppurative ostitis at the junction of the epiphyses and diaphysis. Other signs of congenital syphilis will help to establish the diagnosis. The disease runs a rapid course, and the joint is frequently destroyed. In the adult a chronic plastic synovitis, due to gummatous infiltration of the perisynovial tissue, or of the bone and periosteum, is the more common form. There is very little fluid effusion within the joint, but considerable impairment of mobility is produced by the thickening outside it. The progress of the disease is slow and painless, except at night or on motion. The history of the case; the presence of traces of syphilis elsewhere; and the effects of treatment, will help in establishing the diagnosis. The internal administration of mercury and iodide of potassium, combined with local pressure by means of strapping with mercurial plaster, speedily effects a marked improvement and cure.

WILLIAM MACCORMAC.

JUGULAR VEINS, Physical Signs in connexion with.—The principal physical signs in connexion with the jugular veins are distension, pulsation, and venous hum. See *PHYSICAL EXAMINATION*.

K

KELOID.—*SYNON.*: Fr. *Chéloïde*, *Kéloïde*; Ger. *Keloid*.—*Keloid* and *cheloid* are two words resembling each other in sound, and sometimes used indiscriminately, but differing altogether in origin and signification. *Keloid* is derived from *καλέ*, a mark or blemish; whilst *cheloid* derives its origin from *χέλη*, a crab's claw. The disease which we now recognise as keloid was first described by Alibert under the name of *hèle*, with the synonyms, *cheloïde* and *caneroloïde*, and is therefore sometimes referred to as the 'kelis

of Alibert' (see *CHELOID*). The term keloid has, however, been applied by Addison to a blemish of the skin, resulting from a fibrous degeneration of the derma allied with scleriosis, hence the use of the term *kelis Addisonii*. Both diseases are really fibromata; but one, namely cheloid, is a tumour, while the other, kelis, is flat, and often resembles a cicatrix. There is another obvious difference between them: cheloid is restricted to the derma, whilst kelis follows the subcutaneous connective-tissue to the deeper parts of the body.

The early dermatologists described kelis under the name of *morpheæ*, and by that name it is still distinguished by some modern writers.

ERASMUS WILSON.

KERATITIS, or KERATODEMITIS (*scaps*, a horn, the cornea).—Inflammation of the cornea. See EYE AND ITS APPENDAGES, Diseases of.

KERION (*kerion*, a honeycomb)—A term applied to a pustular folliculitis of the scalp. The inflamed skin occurs in the form of one or several blotches of a deep red colour, prominent, and dotted over with yellow spots—the apertures of the follicles, from which the hair has been expelled, and which exude a copious mucopurulent fluid. The yellow spots are converted into hollows by the tumefaction of the framework of inflamed skin, and, no doubt, thereby suggested the idea of a honeycomb, whilst the mucopurulent secretion might in like manner be compared to honey. Another feature of the disease is the elimination of the hair from the inflamed follicles, and the subsequent baldness of the affected part. Kerion is sometimes associated with tinea capitis. See SKIN, Diseases of, and TINEA.

ERASMUS WILSON.

KIDNEYS, Diseases of.—SYNON.: Fr. *Maladies des Reins*; Ger. *Nierenkrankheiten*.—The kidney is subject to a number of diseases, which will be considered in the following pages in alphabetical order. At the outset, however, it will be convenient to present an outline of the abnormal phenomena to which these affections may give rise.

SUMMARY OF SYMPTOMS.—The facts upon which the diagnosis in diseases of the kidneys is founded, are of three classes, namely,—A. Abnormal local conditions; B. Abnormalities of the urinary secretion; C. Abnormalities in other parts of the system, secondary to the local phenomena.

A. Abnormal local phenomena. — These may be —

a. *Subjective.* The patient may experience pain or uneasiness in the region of the kidney, on one or both sides, and abnormal sensations may be also referred to the ureter, the bladder, or the urethra. The pain may be influenced by attitude or by exertion, and be either constant, paroxysmal, or periodic. It may be aggravated, relieved, or unaffected by pressure.

b. *Objective.* Examination of the abdomen and pelvis, by means of palpation and percussion, may reveal the presence of a tumour connected with the kidney. The tumour may be solid or fluid; uniform or lobulated. Tumours of the kidney may generally be made out by palpation, and especially by tilting with the one hand the mass forwards from the lumbar region, upon the fingers of the other hand applied in front. In some cases the absence of the kidney from its normal position may be ascertained by percussion in the lumbar region. By careful observation of the relative form of the two sides at the back and in front, either the presence of tumour, or the absence of the organ, may be rendered distinct.

B. Abnormalities of the urinary secretion.—a. The urine may be altered in quantity. It may be increased, as in waxy degeneration of the kidney, or in advanced stages of cirrhotic and inflammatory Bright's disease; or diminished, either from obstruction to its escape, or from failure of secretion. The conditions leading to obstruction to outflow are certain diseases of the urethra, prostate, bladder, or ureter; the last-named inducing suppression only where both the ducts are simultaneously occluded, or where one kidney having been previously destroyed, the ureter of the other side subsequently becomes affected. The impaction of calculi, and the pressure of new-formations are the chief causes of these obstructions. The conditions leading to diminution or failure of secretion are the pyrexial state; obstruction of uriniferous tubules, as by inflammatory products; long-standing passive congestion, as in cardiac disease; and probably some forms of altered innervation.

b. The urine may be altered in colour, as from the presence of blood, pus, bile, purpura; or of substances introduced into the system, such as logwood, rhubarb, senna, tar, and carbolic acid.

c. The specific gravity may be altered, being much raised when the proportion of water is small, or when an excessive amount of sugar or of uric acid is being eliminated, or when a large proportion of blood or of albumin is present. It is diminished whenever the proportion of water is excessive, or the elimination of uric acid diminished. It is thus an important feature of renal disease. In determining the specific gravity it is important to remember that, when the specimen has stood for some time, it may vary in different parts of the same column of fluid, that it varies with the temperature, being lower in warm than in cold fluid; and further that it varies at different times of the day, in relation to the state of the digestion.

d. The reaction of urine varies from the slightly acid standard of health, by being either too acid or alkaline. The acidity may be excessive when the urine is passed, or may become increased after it has been voided, in consequence of the acid fermentation. It may be alkaline when passed, from the presence either of fixed alkali or of ammonia. The ammonia results from decomposition of urea, and this change constantly occurs in urine which has been kept and allowed to decompose.

e. *Albumin* is a common morbid constituent of urine, either temporary or permanent. Temporary albuminuria may be artificially produced by the ingestion into the stomach, or by subcutaneous injection, of raw albumin of egg; and it sometimes results from derangement of the digestion, due to the use of indigestible articles of food. It occurs in certain blood-diseases, such as scarlet fever, erysipelas, diphtheria, and acute yellow atrophy of the liver, and is probably due to the irritation of the kidneys by the poisons proper to these maladies. It also occurs in some cases where fever is high and persistent, and is then to be explained by alteration of the condition either of the vascular walls, of the renal cells, or of the innervation of the kidneys. It also occasionally results from the use of certain drugs, such as turpentine and cantharides; certainly sometimes

from nervous affections, such as exophthalmic goitre, epilepsy, and injuries to or organic disease of the brain. Permanent albuminuria is met with in all the forms of Bright's disease; most abundantly in the inflammatory form; to a less extent, but constantly, in the albuminoid; to a still less extent, and sometimes altogether absent, in the cirrhotic variety. It also results from passive congestion of the kidneys, due to cardiac disease or other cause; as well as from suppurative nephritis and other diseases of the kidney, and from pyelitis. The ordinary albumin of the blood-serum is the form which usually appears in the urine. Now and then it is found, especially in the course of or after acute febrile diseases, that a variety of albumin occurs in the urine which is unaffected by heat and nitric acid, but which becomes coagulated by alcohol. This may either be from alteration of the substance itself, or from the presence of some material which interferes with the ordinary chemical reaction. See ALBUMINURIA.

f. Urea is diminished in quantity wherever there is destruction of the renal epithelium, as in the different forms of Bright's disease, especially the cirrhotic and inflammatory varieties.

g. The physical and chemical characters of the urine are often much modified by conditions other than diseases of the kidneys themselves, and abnormal ingredients may be present, such as sugar or bile, but these alterations do not come within the scope of the present article.

h. Deposits are also frequently present in the urine, which are due to various causes apart from renal disease, namely, urates and uric acid, oxalate of lime, phosphates, cystine, xanthine, tyrosine, and leucine. Organic deposits are important in many affections of the kidney or its pelvis. In the first place the *epithelium* from the latter may be present in more or less abundance. Pus appears as a fine granular yellowish deposit, which becomes viscid and transparent on the addition of liquor potassae. In ammoniacal urine it is sometimes found that the pus-cells have undergone this change within the bladder. Pus may be derived from the pelvis of the kidney, or from the kidney-substance itself. Deposits very similar in general appearance to pus are sometimes seen in cases of scrofulous kidney, but the microscopic appearances are different, the corpuscles being altered, and often associated with fibrous tissue. Cancerous deposits, showing distinct cancer-cells, are also sometimes met with. The presence of *blood* gives the urine a smoky, pinkish, or actually bloody appearance. See HÆMATURIA.

Tube-casts are sometimes so numerous as to constitute a deposit quite visible to the naked eye. These casts are solid moulds of the uriniferous tubules, sometimes formed within the free lumen of the tube, but far more frequently within the basement-membrane, thus including the more or less altered epithelium. The simplest form of tube-cast is the hyaline, a clear structureless cast. Blood-casts are common, containing distinct red corpuscles. Epithelial and desquamative casts are opaque and granular, the granularity being due for the most part to the abundance of altered epithelium in their substance. Fatty casts are those which exhibit evidences of fatty

degeneration of the epithelium. See BRIGHT'S DISEASE; CASTS, and URINE, Morbid Conditions of.

C. Symptoms occurring in other parts of the body.—Very important symptoms occur in connection with renal diseases, affecting the organs of circulation and of digestion, the nervous system, and the skin; but these are for the most part associated with Bright's disease. See BRIGHT'S DISEASE, and URÆMIA.

The several diseases of the kidney will now be indicated and those will be discussed which are not described under special headings in other parts of the work.

1. Kidney, Abscess of.—SYNOV. Renal abscess.—This is often used as a generic term including any accumulation of pus in connection with the kidney whether in the substance of the organ, in its pelvis, or even around it. Strictly, it applies only to a collection of matter resulting from suppuration in the kidney-structure itself. See Kidney, Inflammation of Pelvis of; Kidney, Suppurative Inflammation of; PERINEPHRITIS, and SURGICAL KIDNEY.

2. Kidney, Acute Atrophy of.—DEFINITION. This is a rare disease of the kidney, consisting in rapid exudation into the cells of the organ, followed by fatty degeneration and disintegration; caused by unknown conditions; characterised by sudden occurrence of copious albuminuria, with very numerous tube-casts, and frequently marked uræmic symptoms; and resulting apparently invariably in death.

ETIOLOGY.—The causes of this affection are unknown, but it appears probable that it depends upon some form of blood-poison, the disease being frequently associated with acute atrophy of the liver. In most cases it would appear to follow the hepatic disease; in some it precedes it. It is much more common in the female sex than in the male, and is most frequent during pregnancy and after childbirth.

ANATOMICAL CHARACTERS.—There are two stages in the progress of this disease, namely, (1) that of exudative infiltration and enlargement; (2) that of disintegration and atrophy. In the first stage the organ is enlarged, not markedly congested, the capsule strips off readily, the substance is flaccid, the cortical substance is swollen, the individual tubules are enlarged and white. On section the vessels are found mostly empty of blood, being compressed by the diseased tubules. The tubules are occupied by dense opaque material; and the individual cells are swollen and granular, their nuclei being hidden by molecular cell-contents. The tubules of the cones, as well as those of the cortical substance, are frequently affected. Many of the coils also are in a state of fatty degeneration, or broken down even at this stage. In the more advanced stage the organ is smaller than natural, and its capsule appears wrinkled. The kidney is pale and flaccid. When cut into there escapes a quantity of debris, often containing oil-globules, quite visible to the naked eye. The stroma is intact, and sections can easily be made with a Valentin's knife. The sections show that many of the tubules are denuded of epithelium, and that the shrinking of the organ results

from this disintegration. It is easy to find different tubules and cells in various stages of transformation, some showing the early stage of cloudy swelling, others the stage of fatty transformation, and others the disintegrating, almost deliquescent condition. The friability of the cells is quite extraordinary, the weight of a thin covering glass often sufficing to reduce them to molecular debris.

It will be observed that the changes, both in the organ and the individual cells, exactly correspond to those met with in acute atrophy of the liver.

SYMPTOMS—The symptoms characterizing this affection have not yet been very fully studied. Diminution of urine, copious albuminuria, with deposit of casts corresponding to the changes in the kidney, are probably the chief renal symptoms. A tendency to hæmorrhages, jaundice, and uræmic nervous affections, and the series of symptoms proper to acute atrophy of the liver, are also observed.

DIAGNOSIS.—There is probably no disease with which this is very liable to be confounded.

PROGNOSIS AND TREATMENT.—The prognosis must be unfavourable; and no treatment can be of any avail.

3. Kidney, Albuminoid Disease of. See BRIGHT'S DISEASE.

4. Kidney, Anomalies of—The kidneys may present three kinds of anomaly, namely — 1. In number. 2. In form. 3. In situation. Only the first of these will be referred to here.

Anomalies in Number.—Sometimes one kidney, with the corresponding ureter, is entirely absent. In such cases the organ which is present is much above the normal size. There is generally no symptom present during life, but diseases of the pelvis of the kidney or the ureter are made more formidable in persons so affected, than in those normally developed. Occasionally one or more supernumerary kidneys are present. See Kidney, Malformation of, and Kidney, Malpositions of.

5. Kidney, Calculus in. See RENAL CALCULUS.

6. Kidney, Cancerous Disease of. See Kidney, Malignant Disease of.

7. Kidney, Chronic Atrophy of.—This condition of the kidney arises under a variety of circumstances, but specially as a consequence of hydronephrosis, and of the different forms of Bright's disease. In hydronephrosis the atrophy commences in the cones, and spreads to the cortical substance. In all the forms of Bright's disease it commences at the surface and spreads inwards. In hydronephrosis atrophy is a result of the pressure of the renal secretion, as it accumulates in the dilated pelvis and within the tubules. In inflammatory Bright's disease it is due to interstitial changes, and the gradual absorption of the contents of the occluded uriniferous tubules. In cirrhotic Bright's disease it is a consequence of the contraction of the hypertrophied fibrous stroma, and the consequent destruction of vessels and secreting structures. In the waxy or albuminoid form it is due to the molecu-

lar absorption of the hyaline material and altered cells which occupy the uriniferous tubules, as a consequence of the degeneration proper to the vessels.

ANATOMICAL CHARACTERS.—Although really atrophied, the hydronephrotic kidney appears large, and may form a mass several times the size of the normal kidney. It is lobulated on the surface, and may often be seen to be little more than a group of cysts containing watery fluid. In the earlier stages no change is observed, except flattening of the cones, in the later the cortical substance also is more or less wasted. This condition is usually seen only on one side, the other kidney being natural, or somewhat hypertrophied.

Atrophy from inflammatory Bright's disease is rarely far advanced when the fatal result occurs. Both kidneys are affected, and usually to the same extent. The capsule strips off readily. The surface presents a finely granular appearance. On section, the cortical substance is found relatively diminished. Many of the tubules are occupied by sebaceous-looking material. Many of them are diminished in size, and irregular in outline from absorption of their contents. The stroma is relatively increased; the vessels are little altered.

In the cirrhotic form the atrophy is often more advanced, and is commonly equal, or nearly so, on the two sides. The capsule is adherent, the surface granular and uneven. On section, the cortical substance is diminished, and it often contains many cysts. On microscopic examination the fibrous stroma is found markedly increased, many of the tubules and vessels are destroyed, while the smaller arteries are thickened.

In the albuminoid form the kidneys have in some cases been found greatly and nearly equally diminished in size. The capsule strips off readily; the surface is finely granular. On section the cortical substance is found diminished, the degenerated Malpighian bodies remaining singularly prominent, especially towards the surface, the stroma appearing relatively somewhat increased, and the hyaline contents of the tubules in process of absorption.

SYMPTOMS.—No definite group of symptoms indicate the existence of atrophy. Those met with in the atrophic stages of the different affections are described under each disease.

Partial Atrophy of the Kidney results from embolism, new-formations, and other like causes, and is in many instances unattended by symptoms.

8. Kidney, Cirrhotic. See BRIGHT'S DISEASE.

9. Kidney, Congestion of. See Kidney, Hyperæmia of.

10. Kidney, Cystic Disease of.—**DEFINITION**.—A chronic morbid state of the kidney, caused by conditions not fully ascertained; characterised in some cases by no symptoms, in others by the presence of tumours, and by symptoms resembling those of the cirrhotic form of Bright's disease; resulting in permanent change; and not amenable to treatment. The formation of cysts in the kidney may be uni-

portant, either from the small number of cysts, or from the co-existence of much graver disease of the kidney; but it may constitute a serious disease.

Ætiology.—Nothing is known as to the causes of cystic degeneration. It may be congenital, or may come on during adult life. The mode of origin of the cysts appears to be from the dilatation above obstructed points in the course of uriniferous tubules, or at their points of origin in the Malpighian bodies. Sometimes the cysts are new formations in connection with epithelium, and sometimes they arise from the fibrous stroma of the organ.

ANATOMICAL CHARACTERS.—Renal cysts vary greatly in size, from minute, almost microscopic, cavities, to spaces capable of holding several pints of fluid. The true cystic kidney is large, its surface is uneven, and in colour resembles a piece of conglomerate. The capsule strips off, but often with some difficulty. On section its substance is found replaced by multitudes of cysts, scarcely any proper tissues remaining. The contents are sometimes watery, sometimes contain urinary constituents, sometimes are tinged with blood, and sometimes are gelatinous or colloid.

SYMPTOMS.—In many cases cystic disease of the kidneys is unattended by any symptoms, and even when the disease is extensive and severe there are, as a rule, no constitutional symptoms until the case draws near its termination. Among local signs the most important is enlargement of the organs, which may sometimes be made out by means of palpation and percussion, in cases which are advanced, and in emaciated subjects. Both organs are generally equally enlarged. The urine is secreted in natural or in excessive quantity; its specific gravity is low; and it contains albumin, and sometimes blood. The termination of these cases is not unfrequently abrupt, with uræmic convulsions and coma.

DIAGNOSIS.—The points which are of importance are the presence of bilateral tumour, with copious discharge of urine of low specific gravity, or containing albumin.

PROGNOSIS.—The prognosis is always unfavourable.

TREATMENT.—Treatment can be directed only to the relief of symptoms.

11. **Kidney, Dropsy of.**—This is a synonym for hydronephrosis, in which urine, more or less altered, accumulates in the renal pelvis, as the result of obstruction of the ureter. See **HYDRONEPHROSIS**.

12. **Kidney, Embolism of.**—The impaction of emboli in the branches of the renal arteries gives rise to various lesions, of which the most common is the hemorrhagic infarction; next to this inflammation and secondary abscesses; and more rarely gangrenous inflammation. These affections often do not manifest themselves during life by any distinct symptoms; or their existence may be revealed by sudden albuminuria and hæmaturia, and sometimes by general constitutional disturbance and local pain.

6. **Ætiology.**—The chief cause of renal embolism is disease of the valves of the heart. The emboli may be composed of coagulated fibrin,

or of fragments of the tissue of the valve, which have been separated by ulceration. More rarely embolism is caused by fibrin which has coagulated between the meshes of the fleshy columns of the heart, or by coagula which have formed on the roughened inner coat of arteries. Among the remoter causes are those of endocarditis and endarteritis. This, in so far, vindicates the name which Rayer applied to these infarctions—*reumatismal nephritis*.

ANATOMICAL CHARACTERS.—1. *Of hemorrhagic infarction.*—This may, for convenience, be described as passing through three stages:—(1) that of red consolidation; (2) that of fawn-coloured transformation, and (3) that of absorption or atrophy. The form of the masses is usually conical, or, as seen on section, wedge-shaped, the base being towards the surface. At first a patch is deeply congested, and presents a dark red colour. On microscopic examination the vessels are found congested, many ruptured, and blood is extravasated into the tubules. In the second stage this redness has passed away, a buff or fawn-coloured mass represents the red patch of the earlier stage. On microscopic examination the cells of the tubules are found to be destroyed, and within them, as well as in the stroma, blood-pigment may be found. In the third stage there is commonly a depression of the surface of the organ; and, on section, what had been the conical patch is represented by a fibrous cicatrix.

2. *Of the abscesses.*—In certain cases, especially in the course of pyæmia, emboli lead to abscesses. Throughout the organ such abscesses exist, and may be traced in various stages, which might be described as those of red consolidation, of ashy-gray consolidation, and of suppuration. In this condition the clot is not to be found at the apex of the cone of disease, but imbedded within it. Between the simple infarction and the abscess there is an intermediate form—a certain degree of suppuration occurring at the margin of the affected area.

3. *Of gangrenous patches.*—Very rarely it appears that, in consequence of the impaction of an embolus, gangrene of the affected district occurs, with more or less suppuration.

SYMPTOMS.—The symptoms of the embolic infarction are often very indistinct, but the condition may sometimes be diagnosed. When valvular disease of the heart or extensive calcareous affection of the arteries exists, and when in addition to this sudden albuminuria or hæmaturia appears, with some degree of fever, and pain in the region of the kidneys, there is every reason to conclude that an embolus has been impacted. This condition is rarely one of importance in the case, for much graver maladies co-exist with it. The occurrence of abscess in the kidney may sometimes be surmised when sudden albuminuria or hæmaturia becomes superadded to the other symptoms of pyæmia. Gangrene of the kidney or a portion of it is not likely to be capable of diagnosis during life.

6. **DIAGNOSIS.**—The diagnosis of renal infarction turns upon the points above referred to. It is important to distinguish it from Bright's disease, and from passive congestion. From the former it is distinguished by the suddenness of

the onset, the shortness of its duration, the absence of dropsy, and the presence of cardiac or vascular disease; from the latter by the suddenness of its development, and by the absence of signs of stasis in other organs.

Prognosis.—The prognosis in cases of infarction is favourable so far as the kidneys and their functions are concerned, but unfavourable in this respect that there is a tendency to the impaction of emboli in other more important parts, particularly in the brain.

Treatment.—No special or particular treatment can be directed in this condition.

13. Kidney, Fatty Disease of.—**Definition.** A chronic affection of the kidney, consisting in simple fatty degeneration of, or infiltration into, the renal epithelium, without inflammation; characterised by no symptoms as yet clearly ascertained.

Ætiology.—Fatty kidney results in some cases from long-continued exhausting disorders, from senile marasmus, from starvation, from poisoning with phosphorus, and perhaps from excessive indulgence in fatty food.

Anatomical Characters.—The organs are of about the natural size, their surface is smooth, and the capsule strips off readily. There is no congestion, and scarcely any stellate veins are visible. The organ is more soft and flexible than natural, and the surface is mottled with numerous deposits of sebaceous-looking material. On section the relative size of the cortical substance and the cones is soon to be preserved, and beyond a general pallor there is no change except the abundant deposition of sebaceous-looking material, mostly in the tubules of the cortical substance, but also in those of the cones.

On examining a section with a low power of the microscope, the characteristic fatty opacity is well-marked, and by careful scrutiny it may be generally made out that the fatty material is not in the canal of the tubule, but within the epithelial cells. The Malpighian bodies, the vessels, and the stroma, under a higher power, appear natural, and in transverse section of the tubules, a clear lumen may be made out. It will thus be observed that there is no inflammatory desquamation of the cells, nor exudation filling up the lumen of the tube.

Symptoms.—Little is known of the clinical features of this affection. But the quantity of the urine appears to be diminished. There is certainly no albuminuria, and apparently no other important change in its composition. Dr. Lang, of Dorpat, has shown that a little free oil is sometimes found in the urine.

Diagnosis.—It is scarcely possible to diagnose this affection with certainty, but diminution of the urine, without albuminuria, and with the presence of oil in the urine, especially if associated with the signs of fatty liver, and with any of the known causes of fatty degeneration, may lead to the establishment of the diagnosis.

Prognosis.—The renal affection is not generally an important element in the prognosis, other conditions of more importance being present.

Treatment.—General tonic treatment, and the removal of the cause when known, are the only indications.

14. Kidney, Gouty.—This is a form of contracted granular kidney, occurring in gouty subjects, and attended with the deposit of urates in the renal tubules. *See* BRIGHT'S DISEASE; and GOUT.

15. Kidney, Granular.—A synonym for a chronic form of Bright's disease, where the kidney presents a granular appearance. *See* BRIGHT'S DISEASE.

16. Kidney, Hemorrhage in connection with.—Blood may escape into the substance of the kidney, as the result of embolism or injury; into the tubules, giving rise to blood-casts; or into the renal pelvis, especially from injury to the mucous lining by calculi. The only diagnostic indication of this event is the presence of blood in the urine, intimately mixed with it, or sometimes in clots. A coagulum of blood may block up the ureter. *See* HÆMATINURIA, PAROXYSMAL, and HÆMATURIA.

17. Kidney, Hydatid Disease of.—**Definition.**—A chronic parasitic disease of the kidney, caused by the reception into the system of the ova of the *Tænia echinococcus*, and the development in the kidney of the corresponding cystic form, consisting in the formation of hydatid cysts—'*echinococcus hominis*'—in the substance of the organ, characterised in some cases by no symptoms, in others by renal tumour, or by the discharge of cysts with the urine, after symptoms resembling those of renal calculus; and resulting sometimes in recovery, sometimes in death, either by perforation into the lung, intestine, or other part, or by suppuration.

Ætiology.—The tape-worm form is the *Tænia echinococcus*, which inhabits the intestine of the dog. The frequency of hydatid-disease is determined by the frequency of the occurrence of the tape-worm in the dogs, and by the habits of the people. It is common in Iceland, in Egypt and in South Australia. In England it is not common, in Scotland it is very rare. *See* HYDATID.

Anatomical Characters.—The affected organ is enlarged, sometimes greatly. It is often connected by adhesions to neighbouring parts. A globular tumour projects from the surface, and extends into the substance of the kidney, inducing corresponding atrophy. The cyst has an outer covering of fibrous tissue derived from the organ; and an inner coat—the cyst proper, which may be barren, that is, devoid of daughter-cysts, or may contain within it numerous smaller cysts and processes growing inwards from the walls, containing scolices which may give origin to the corresponding tape-worm. In either case the cyst-wall is somewhat tensely expanded by a clear liquid, rich in chloride of sodium. The cyst enlarges gradually, and may burst in various directions, but most frequently into the pelvis of the kidney, or into the lungs and bronchi. Sometimes suppuration of the cyst occurs, and accordingly one finds on *post-mortem* examination the remains of a shrivelled and sunken cyst, with caseated contents, in which are imbedded remains of daughter-cysts and hooklets from the scolices.

Symptoms.—The course of hydatid-disease of the kidney is always chronic. It may be pro-

longed for many years. The advance is insidious. Attention is sometimes drawn, first to the presence of a tumour, sometimes to the evidences of its rupture. When rupture takes place into the pelvis of the kidney, daughter-cysts passing along the ureter give rise to symptoms resembling those of renal colic; but the discharge of the cysts, and the results of the microscopic examination, reveal the true cause of the irritation. After such a discharge the cyst may atrophy, sometimes it happens that a second or even a third discharge occurs after a shorter or longer interval. When the discharge is by the lung, pain and cough occur, due to irritation of the pleura. Then the expulsion of the hydatids takes place, sometimes this also results quite favourably. The special features of a hydatid tumour are its globular form and its elasticity. When suppuration occurs, fever supervenes, attended with local pain.

DIAGNOSIS.—The diagnosis of hydatid of the kidney depends upon the presence of a tumour of a special kind; and is made certain by the discharge of cysts or hooklets.

PROGNOSIS.—The prognosis is always doubtful.

TREATMENT.—Medicine is of no avail. The best treatment is the removal of the fluid contents of the cyst by aspiration. When such removal is effected the parasites die, and the cyst shrivels up.

18. Kidney, Hypersemia of.—DEFINITION.

An acute or chronic affection of the kidney, consisting in active or passive congestion of its vessels, with secondary changes, characterised by the appearance of albumin, and sometimes of blood and of hyaline tube-casts in the urine, the quantity of urine being generally diminished, and its specific gravity natural; resulting in recovery if the cause be removed, but in the passive form commonly continuing or recurring till the fatal result is induced, partly by the original, and partly by other causes.

ÆTIOLOGY.—Active congestion, that is congestion due to increased influx of arterial blood, may be caused by inflammation; by various blood-poisons, such as those of scarlet fever, measles, typhus; and by some medicinal substances, such as cantharides, turpentine, opium; also probably by agencies which paralyse the muscular fibres of the small arteries—as is sometimes seen in the course of exophthalmic goitre—or which increase the blood-pressure in the renal arteries. Passive congestion, which implies congestion due to hindrance to the efflux of venous blood from the organ, may be caused by any obstruction to the circulation. It is most commonly met with in cases of cardiac disease, where the right chambers of the heart are dilated. It also results from such diseases of the lungs as are followed by dilatation of the right side of the heart—for example, emphysema. It also sometimes arises, though much more rarely, from obstruction in the course of the inferior vena cava, or in the renal veins, as from pressure of aneurismal or other tumours, or from the formation of a thrombus.

ANATOMICAL CHARACTERS.—In the active form of renal hypersemia, the anatomical changes are probably less marked after death than during

life. The kidneys are generally of fully the normal size; the capsule strips off readily; and the surface is smooth. On section the vessels are found congested, the Malpighian bodies frequently standing out prominently, being distended with blood. The vessels of the cones are also overfilled. More or less evidence of inflammatory change is to be found in the tubules—the epithelium being granular and opaque, and the lumen of the tubules, especially those of the cones, being filled up with coagulated fibrin. Blood is sometimes found extravasated into the convoluted tubules. The stroma is unaltered. Sometimes there is congestion of, or even extravasation into the mucous membrane of the pelvis of the kidney and of the ureter. In passive congestion the anatomical changes are more marked, and vary with the duration and intensity of the affection. In the alighter forms, or in those of short continuance, the kidney is of fully the natural size; its capsule strips off readily, the surface of the organ is smooth; and there is evidence of congestion. On section, the congestion is seen to occupy the veins and the Malpighian bodies, sometimes there are evidences of extravasation of blood; and sometimes fibrinous coagula are found in the tubules.

In the more chronic forms, although the capsule strips off readily, the surface is somewhat uneven; congestion is still marked on the surface, but scarcely so distinctly as in the earlier stage. On section the organ feels firmer than natural, it is in a condition which may be best described by the term induration. Its small veins and Malpighian bodies are dilated and full of blood, the fibrous stroma is relatively increased, especially towards the surface of the organ, some of the tubules are wasted, some are blocked up with exuded material, and some exhibit evidence of disintegration and fatty degeneration of the epithelium. The condition of the stroma thus approaches that of cirrhosis of the kidney; the condition of the tubules approaches that of inflammation. There is no definite boundary line between the conditions anatomically; still the combination of the changes confirms the inference which must be drawn from the study of the clinical history, that these hyperemic changes, though approaching to, are not identical with the processes properly included under the term 'Bright's disease.'

SYMPTOMS.—The symptoms of active congestion are the presence of albumin in the urine, occasionally accompanied by hyaline tube-casts, and sometimes by blood in greater or less quantity. It occurs commonly as a transient, or occasionally, as a recurring condition, and unless when it betokens a commencing inflammatory action, is rarely of much practical importance.

In passive congestion albuminuria is again the leading symptom; the urine is generally somewhat reduced in quantity, of about normal specific gravity, often of acid reaction, depositing urates. The amount of urea is little below the normal. Tube-casts are usually scanty, and may be wanting; when present they are hyaline or sometimes bloody, and occasionally contain altered epithelium. The other symptoms are those of obstruction to the circulation, occlusion of, or pressure on, the veins; disease of the

heart; emphysema of the lungs; and general dropsy.

DIAGNOSIS.—The question relating to diagnosis, which is of most practical importance, lies between hyperæmia and inflammatory Bright's disease. In making this distinction, the points to which we have to attend are the general condition of the patient, in respect to the possible causes of such an affection, the presence of cardiac or pulmonary disease, or of venous obstruction. In congestive affections the urine is scanty, as it often is in Bright's disease, but it is of high colour, of natural specific gravity, and rarely deposits blood, renal epithelium, or tubercles.

PROGNOSIS.—The prognosis depends entirely upon the conditions inducing the congestion. In the active form it usually rapidly subsides, in the passive form, it is persistent, or at best, if temporarily got rid of, is almost sure to recur.

TREATMENT.—When the renal congestion is very intense, dry cupping, local blood-letting, the hot air or the warm vapour bath, or warm applications over the kidneys, may be indicated, but the treatment is mostly that of the diseases which are inducing the congestion. Thus, in the case of cardiac disease digitalis and iron, in the case of pulmonary disease digitalis with squill, and if necessary, a little blue pill or carbonate of ammonia, are indicated. The general management should be that proper to the obstructive disease which has induced the congestion.

19. Kidney, Hypertrophy of.—True hypertrophy, that is to say, increase of all the elements, or of the essential elements of the kidney occurs only in one organ as a rule, and that by way of compensation for atrophy of the other.

Simple increase of bulk of the kidneys often results to a certain extent from congestion, inflammation, the various forms of Bright's disease, new formations, and accumulation of the secretion.

ANATOMICAL CHARACTERS.—These present no peculiarity beyond the enlargement, the organ weighing sometimes eight or nine ounces, the renal artery and vein being proportionately enlarged, with a corresponding coarseness of structure.

SYMPTOMS.—Hypertrophy of the kidney is without symptoms, but it might so happen that the enlargement of the organ could be detected on physical examination.

20 Kidney, Infarction in.—See Kidney, Embolism of.

21. Kidney, Inflammations of.—Inflammation of the kidneys and their pelves presents many varieties. The kidneys themselves exhibit, first, tubular inflammation, acute or chronic; second, inflammation of the stroma, acute or chronic; third, suppurative inflammation of the substance of the organ, septic or non-septic. The renal pelvis is also liable to acute or chronic inflammation. It will serve no useful purpose to discuss these in a general article, and therefore the reader is referred to the several special articles. See BRIGHT'S DISEASE, Kidney, Suppurative Inflammation of; and Kidney, Inflammation of Pelvis of.

22. Kidney, Inflammation of Pelvis of. SYNON.: Pyelitis; Fr. *Pyélite*; Ger. *Nierenbeckentzündung*

DEFINITION.—An acute or chronic disease of the pelvis of the kidney, caused by extension of inflammation or of irritation from the neighbouring parts, by renal calculus, by cold, or by blood-poisoning, consisting in inflammation of the mucous membrane, frequently associated with changes in the other coats and in neighbouring parts, characterised by the presence of mucus or pus in the secretion, with local pain, and more or less constitutional disturbance; sometimes resulting in recovery, sometimes in long-continued illness, and occasionally in death.

ÆTIOLOGY.—Pyelitis is caused by:—(1) extension of inflammation from neighbouring parts of the urinary tract sometimes from the kidneys, sometimes from the bladder; (2) stagnation and decomposition of the urine in the renal pelvis, (3) mechanical irritation, as from calculi and gravel, (4) exposure to cold; (5) certain blood-poisons, such as those of pyæmia, diphtheria, and typhus, (6) the action of certain other poisons.

ANATOMICAL CHARACTERS.—Three types of pyelitis may be recognised, namely:—(1) the acute, (2) the chronic, and (3) the calculus.

(1) *Acute*.—The mucous membrane is congested, and its surface coated with mucus, sometimes with a bloody, sometimes with a diphtheritic layer. The membrane itself may be more or less extensively destroyed, and the characteristic tailed cells of the pelvis of the kidney may be thrown off in excessive quantity. Besides these cells, the cavity contains mucus or muco-purulent material in quantity.

(2) *Chronic*.—In this condition the mucous membrane is much thickened, often of a slate-grey colour, with ecchymoses, and sometimes with ulcerative abrasions of the surface. The other coats of the pelvis and ureter may also be distinctly thickened, and the lumen of the ureter may be more or less narrowed. The cavity contains purulent material, with debris of broken-down mucous membrane; and sometimes, the ureter being obstructed, great accumulation of pus takes place, so as to expand the pelvis and lead to partial atrophy of the kidney (*pyonephrosis*).

(3) *Calculus*.—In this form the mucous membrane may present either of the conditions above described, but one always finds mingled with the other materials calculi of greater or less size.

SYMPTOMS.—The symptoms of acute pyelitis may be either well-defined, or masked. There may be uneasiness or acute pain in the loins and along the line of the ureter; sometimes distinct rigors, with other febrile symptoms, occur; and the urine is cloudy, depositing mucus or muco-purulent material, or sometimes blood. The most characteristic feature is the presence in the urine of the angular tailed cells which line the pelvis of the kidney. The condition may gradually subside, or may become chronic; or in rare cases, and where important complications exist, it may prove fatal.

In chronic pyelitis there is often an aching feeling, or well-defined pain in the region of the

ureters. There is constitutional disturbance, debility, fever, hectic; the urine is opaque, and deposits pus—generally grey, sometimes tinged with blood. This condition may go on for long periods, sometimes terminating in recovery, but often persisting and proving fatal by exhaustion, by extension to the kidney-substance or to the cellular tissue, or by concomitant complications.

The *calculous* form differs from the others in respect of its cause; and in being attended by more pain, by more tendency to hemorrhage, and sometimes by the presence of crystals, gravel, or calculi in the deposit.

If the escape of the pus should be prevented in any of the three forms of pyelitis, owing to obstruction of the ureter, and pyonephrosis result, a fulness or fluctuating tumour may be detected in the renal region, and this in some instances embodes at intervals, with a copious discharge of pus in the urine.

DIAGNOSIS.—From cystitis, pyelitis is distinguished by the absence of vesical pain, and of frequent calls to micturition; and by the presence of the lumbar uneasiness, and the more intimate admixture of the foreign materials with the secretion. From renal inflammation it is distinguished by the absence of tube-casts; the seat of the pain, and the presence of the characteristic cells of the renal pelvis. From strumous kidney it is sometimes almost impossible to differentiate simple pyelitis. Indeed the two conditions are not infrequently associated together, but the presence of other evidences of strumous disease, the enlargement of one or both kidneys, and the presence of copious *debris*, in addition to the pus, often suffice to distinguish the one from the other.

PROGNOSIS.—In the slighter and acute forms of pyelitis, the prognosis is generally favourable. In the chronic variety it must always be guarded, the amount of danger being determined in some measure by the cause, the constitutional conditions, and the complications.

TREATMENT.—The first essential is that the patient should have rest, and that the urinary secretion should be copious and bland. In order to secure this a diet largely composed of milk and simple diluents, or in some cases exclusively of milk, and the avoidance of stimulating foods and drinks, are to be insisted on. As to medicine, if the urine be excessively acid, alkalies should be administered; if it be alkaline, mineral acids should be given. Various remedies which appear to diminish irritation, such as the *uva ursi*, *pareira brava*, *uchu*, *triticeum repens*, *copaiba*, and sandal-wood oil, ought to be employed. In the acute cases the application of poultices to the loins, and the internal administration of benzoin or opium, are to be recommended.

In the chronic forms of pyelitis a similar line of treatment should be perseveringly followed; and in cases which owe their origin to the presence of calculi, the remedies appropriate to the diathetic condition should be employed. Astringents may possibly be useful in checking too copious a discharge of pus.

23. Kidney, Malformations of.—The commonest malformation of the kidneys is *lobulation*, which is a relic of the fetal condition.

Next comes the undue development of one organ. Sometimes there are two pelves belonging to each kidney, or two ureters. A not very rare anomaly is the *horse-shoe kidney*, which consists simply in the union of the two kidneys, by a band of renal tissue, at either end, usually the lower. This abnormality is often attended by anomalies in the arrangement of the ureters and vessels. A very rare condition is that in which there is a *central antrum* between the two organs, owing to the development of supplementary renal structure opposite their pelves. None of these malformations lead to any important symptoms, except by pressure upon the duct or vessels, under superadded abnormal conditions of the organs themselves, or of neighbouring parts.

24. Kidney, Malignant Disease of.—**DEFINITION.**—A chronic disease of the kidney, caused by the circumstances which induce cancer elsewhere; consisting in the formation of nodules of cancer, or the infiltration of the organ with the new formation; characterised by a renal tumour, cachexia, and frequently by alteration of the urine; and resulting in death.

ÆTIOLOGY.—*Primary* renal cancer arises from causes not yet ascertained. It occurs at two epochs of life, namely, in early childhood and in adult age. Children under four years appear specially liable. The male sex is more frequently affected than the female; the right kidney more commonly than the left.

Secondary cancer of the kidney is most frequently associated with carcinoma of the liver, the stomach, the mamma, the testicle, or the uterus; sometimes of the supra-renal bodies, or the mesenteric glands.

ANATOMICAL CHARACTERS.—All the varieties of cancer have been met with in the kidney, but the medullary is by far the most common. It is sometimes primary, sometimes secondary. The *primary* affects usually one kidney, most commonly the right; the organ is often much enlarged, weighing sometimes as much as sixteen or seventeen pounds, and this even in young children. In ten children Dr. Roberts found the average weight 8½ lbs.; in ten adults he found it 9½ lbs. Such large tumours occupy a great part of the abdomen, and push the colon forward. The cancer is in some cases scattered in separate nodules; in others it is infiltrated through the mass. It commences always in the cortical substance, and is developed from the fibrous stroma. In the scattered cases the remaining portions of the kidney are quite sound. The cancer may involve the sub-mucous tissue of the mucous membrane of the pelvis, the ureters, and the veins. The lymphatic vessels and glands also become secondarily affected. Sometimes it affects the peritoneum, colon, and it has even involved the skin.

When the renal affection is secondary, it constantly affects both organs, and rarely leads to such enlargement as is seen in the primary disease. It occurs in the form of numerous nodules, developed in the stroma or along the vessels. The remaining renal tissue is commonly healthy, but it may be inflamed or otherwise altered.

SYMPTOMS.—The symptoms of primary cancer generally become quite distinct when the disease

advance, but in the earlier stages they are very indistinct. The urine itself is, as a rule, natural in quantity, of acid reaction, normal specific gravity and colour; but from time to time blood appears, its amount varying from a mere trace to a very serious hæmorrhage. Sometimes the blood is in clots, and this bleeding may be the earliest symptom; and it occasionally happens that carcinomatous elements may be discovered in the urinary deposit, but it is very difficult to be sure of their presence.

Examination of the abdomen reveals the presence of a tumour, occupying and extending from the region of the kidney. The tumour is generally nodulated, of tolerably firm consistence, and dull on percussion. The colon lies in front of the mass, which is capable of being tilted forward by pressure on the renal region. When the left kidney is affected, the spleen is displaced upwards. As a rule, there is persistent constipation, and some pain, together with the general symptoms of the carcinomatous cachexia.

DIAGNOSIS.—Carcinoma of the left kidney may be confounded with enlargement of the spleen, with perinephric abscess, perhaps sometimes with disease of the mesenteric glands, or with obstruction of the colon, and retention of feces.

From splenic tumour it is distinguished by its lower position, and the absence of the splenic notch; the normal condition of the blood; and the presence of blood in the urine; also by the nodulated character of the tumour itself, and by the position of the colon.

From perinephric abscess it is distinguished by the absence of fever, and of fluctuation; as well as by the less rapid advance of the disease.

From tumours of the mesenteric glands renal cancer is distinguished by its situation, being more towards the side and the lumbar region. The mass also is less nodular than in mesenteric growths, which are composed of groups of glands.

From carcinoma of the intestine, with accumulation of feces above it, it is distinguished by the position of the mass, and by its characters on palpation; as well as by absence of the signs proper to the intestinal disease.

Carcinoma of the right kidney may be confounded with tumour of the liver, especially in children, but the presence of a space of clear percussion, more or less extended between the liver and the tumour, should remove all doubt. If the diseased kidney touches the liver, reliance must be placed on the symptoms proper to renal or to hepatic disease.

Cancer of the kidney is to be distinguished from tumour of the ovary, by its more fixed condition, and the history of its growth.

PROGNOSIS.—The prognosis is in all cases unfavourable; the duration varies with the form of cancer. Dr. Walshe thinks eight months the average, but that probably is too short.

TREATMENT.—Treatment is, of course, merely palliative—morphia, belladonna, henbane, applied externally or injected subcutaneously to relieve pain; ergotine and other preparations of ergot, acetate of lead, and gallic acid to check hæmorrhage; and iron as an astringent and blood-tonic. The bowels require careful attention; and sometimes there may be so much ascites as to warrant tapping.

25. Kidney, Malpositions of.—The kidney may be congenitally displaced, but the important anomaly coming under this head is the *movable kidney*, which demands special consideration.

DEFINITION.—The movable kidney is a condition especially affecting women; consisting in the undue mobility of one, or rarely of both kidneys, characterised in some cases by no symptoms, in others by uneasiness or pain and general nervous disturbance, and by the presence of a tender reniform tumour, with clear note on percussion in the renal region of the affected side; resulting, as a rule, in frequent recurrence of the symptoms without danger to life.

ÆTIOLOGY.—Movable kidney is more common in the female sex, and especially in those who have passed through many pregnancies, but it is not exclusively associated with women, for it occurs (although rarely) in males, and also in children. The right kidney is much more frequently affected—65 out of 91 cases (Elliott). Its occurrence is probably mainly due to laxity of the abdominal parietes, and unusual length, or irregular distribution, of the renal vessels.

ANATOMICAL CHARACTERS.—The kidney is not necessarily changed in its structure, but its position may be altered in any direction.

SYMPTOMS.—In many cases no symptoms occur in movable kidney. But in some, whenever the displacement occurs, much uneasiness or even considerable pain is experienced. The writer has known a man unable to work in consequence of the pain induced by the displacement, and losing a day's work regularly once a week or once a fortnight. The sensations are generally rather of the nature of vague uneasiness than of actual pain, except when the organ is touched, and then there is pain of a peculiar and sickening kind. On percussion over the renal region posteriorly a clear note may be elicited on the affected side, and sometimes a flattening may be made out at the part. The urine sometimes becomes altered during the attacks, depositing mucus and in one case in the writer's practice a little blood. Careful palpation reveals a tumour, of characteristic renal form; and now and then pulsation of the renal artery may be felt. The morbid condition may recur at intervals during many years, and is in some cases apparent for a time, and then absent for a very long period. It is liable to be brought on by effort, but often appears without discoverable cause. Occasionally it is found that the displaced kidney owes its position to the existence of carcinoma or other disease of the organ.

DIAGNOSIS.—The malady may be confounded with tumour of a malignant nature, originating either in the abdomen or the pelvis. The diagnostic points are, the fever; the peculiar tenderness; the mobility; the occasional disappearance; the unrelaxing character of the tumour; and the occurrence of a clear percussion-note and flattening in the renal region of the affected side.

PROGNOSIS.—The prognosis is favourable.

TREATMENT.—The treatment should be by means of bandages or trusses, to support the abdominal walls, and keep up a pressure upon the kidney, so as to retain it in its normal situation. In the case of the working man above referred

to, complete immunity from the displacement was obtained by the use of a bandage with a pad so arranged as to keep up a pressure upon the organ.

26. Kidney, Morbid Growths of.—The only really important morbid growths of the kidney are cancer and tubercle. Syphilitic new formations occasionally occur, but give rise to no characteristic symptoms. Growths of fibrous, fatty, bony, muscular, and glandular tissue have all been met with in a few cases. Hydatid disease may also be mentioned.

27. Kidney, Parasites of.—The parasites which have been described as existing in the human kidneys are Hydatids, *Strongylus gigas*, *Pentastoma denticulatum*, and *Bilharzia hæmatobia*.

The *Strongylus gigas* is a large nematode worm, and is extremely rare in man. The *Pentastoma denticulatum* is the larval form of *P. tenioides*, one of the *Arachnida*. It was found in one case by Wagner. *Bilharzia hæmatobia* is a trematode worm, about three or four lines in length; and inhabits the branches of the portal system, and the minute veins of the pelvis of the kidney, ureter, and bladder. The parasite also affects these structures themselves. So common is it in Egypt, that out of 363 *post mortem* examinations, Griesinger found it 117 times.

SYMPTOMS.—Hydatid-disease gives rise to a tumour. The symptoms produced by the presence of *Bilharzia* in the kidney are hæmaturia, with irritation of the urinary tract. This parasite is the cause of the endemic hæmaturia of certain regions. The other parasites do not originate any definite symptoms.

TREATMENT.—In the treatment of patients afflicted with *Bilharzia hæmatobia*, the internal use of oil of turpentine, and of the extract of the male shield fern, is recommended. It is stated that when the bladder is affected, injections of iodide of potassium, twenty or thirty grains dissolved in tepid water, repeated every second or third day, have been found useful. See *Kidney, Hydatid Disease of*, *Strongylus gigas*, &c.

28. Kidney, Suppurative Inflammation of.—**DEFINITION.**—An acute or sub-acute disease of the kidneys; caused by injuries, extension of disease from the bladder, and perhaps exposure; consisting in inflammation and suppuration in the kidney; characterised by constitutional disturbance, with local pain or tenderness, and various alterations of secretion; and usually resulting in death.

ÆTIOLOGY.—The commonest causes of this disease are renal calculus, leading to inflammation of the pelvis of the kidney; or inflammation of this part, propagated upwards from the bladder or urethra. Next in frequency is pyæmia, which induces metastatic abscesses. Comparatively rarely the inflammation is a result of embolism of the renal arteries; of injuries; and perhaps of exposure to cold.

ANATOMICAL CHARACTERS.—The affected organs are generally above the natural size. The capsule may strip off readily, but often, as it is being stripped, leads to tearing of the substance, and liberation of pus. The surface is frequently

discoloured in patches. The abscesses may be described as passing through several stages. There is first the stage of congestion, with exudation into the stroma of the organ; secondly, the stage of grey consolidation; and thirdly that of suppuration. Occasionally sloughing occurs. Sometimes perinephric abscess results, from perforation of the capsule. Drying up of the pus, with shrivelling of the affected area, is sometimes met with.

Microscopic examination reveals in some cases at an early stage the presence of colonies of bacteria in certain districts within the tubules, causing irritation first in them, then in the stroma, and thus inducing suppuration.

SYMPTOMS.—The most important clinical features of suppurative nephritis are the constitutional disturbance, accompanied by pain in the region of the kidneys, and tenderness on pressure, with scantiness of secretion; the urine being albuminous or bloody, or sometimes purulent, and depositing tube-casts.

DIAGNOSIS.—From pyelitis, suppurative inflammation of the kidneys is distinguished by the presence of tube-casts, and the absence of the characteristic angular cells of the calices of the pelvis. From perinephritis, it is diagnosed by the absence of distinct tumour, and by the history of the case.

PROGNOSIS.—The prognosis is generally grave.

TREATMENT.—The strength should be supported by suitable food, by tonics, and stimulants when necessary, and in some cases benefit may be derived from poulticing, fomentation, or from the application of leeches. Under suitable conditions it might be desirable to open a renal abscess, and evacuate the pus.

29. Kidney, Syphilitic Disease of.—Syphilis may produce in the kidney, as in other organs, congestion, inflammation—either simple or gummatous, with the cicatrices and nodules resulting therefrom, and waxy or amyloid degeneration.

ÆTIOLOGY.—Nothing is known as to the conditions which determine the action of the syphilitic poison upon the kidney.

ANATOMICAL CHARACTERS.—There is scarcely ever an opportunity of studying the appearance of the kidney in cases of congestion—probably over-filling of the vessels, with slight inflammatory conditions of the tubules, is all that would be found. The simple interstitial inflammation is characterised by thickening and swelling of the fibrous stroma, in patches here and there. Gummatous inflammation is rare, but when it does occur, it forms masses of the ordinary gummy character. Either of these conditions may lead to the formation of syphilitic cicatrices, which may appear on the surface of the organ, or be imbedded in the cortical substance. Their formation is attended by the destruction of tubules in the affected parts.

SYMPTOMS.—Albuminuria, slight in amount and of temporary duration, occurring along with other syphilitic congestive affections, has appeared to the writer to indicate renal congestion. Various slight cases of inflammatory Bright's disease, have appeared to be due to the syphilitic poison. The symptoms of the inter-

stitial and gummy inflammations are not ascertained, although probably albuminuria attends them also. The symptoms of waxy degeneration are described under BAIGRT'S DISEASE.

DIAGNOSIS.—The diagnosis of syphilitic disease of the kidney depends upon the co-existence of renal symptoms with evidences of syphilis, while other diseases of the kidney are excluded.

PROGNOSIS.—This is favourable so far as danger is concerned, except in the case of severe waxy degeneration.

TREATMENT.—Iodide of potassium has been found to be useful in this as in other syphilitic affections, at least in the congestive and inflammatory conditions. Should it fail to give relief, the bichloride of mercury may be given in moderate doses, and continued cautiously even when albuminuria is present.

20. Kidney, Tuberculosis of.—**DEFINITION.** A chronic disease of the kidneys and ureters, caused by tubercular infection, or by strumous inflammation of the structures involved, consisting in the formation of nodules of tubercle, or in strumous inflammation of the substance of the gland, and of the mucous membrane, characterized by some constitutional disturbance, sometimes by renal tumour, and by various alterations of the urine, particularly deposit of caseous purulent *débris*, and resulting usually in death.

ÆTIOLOGY.—The direct causes of tubercular disease of the kidney are unknown. It is more common in children and young people than in those more advanced in life, but it—especially the serofulous form—may occur later on. Men are decidedly more frequently affected than women. The kidneys are rarely equally involved; the right is commonly worse than the left. One organ may be quite free from disease.

ANATOMICAL CHARACTERS.—Under this term are included both tubercle proper, and strumous inflammation. Tubercle proper occurs in the form of minute milky nodules scattered throughout the substance of the organ, as a local manifestation of a general true tuberculosis. Strumous inflammation leads to the formation of larger masses, involving either the mucous membrane of the pelvis of the kidney, or the cortical substance. When the former is its seat, it leads to a thickening of the mucous membrane, commencing in patches which gradually extend, and ultimately undergo ulceration. When the cortical substance is affected, the organ becomes enlarged; presents a markedly lobulated surface; and on section conical masses of altered tissue are found to correspond to the prominences of the lobules. Some of them are solid and cheesy; others are softened in the centre, while others are completely softened, so that on section a quantity of puriform *débris* flows out, leaving a cavity with white walls, rendered shaggy by the shreds of fibrous tissue which project from them. Sometimes scarcely any renal structure is left. Occasionally what remains shows the characters of waxy degeneration. The disease commences in the stroma of the organ; the tubules are compressed, but are rarely the seat of inflammatory changes. When the mucous membrane of the pelvis of the kidney and the ureter is affected, the membrane is thickened at

certain parts, and afterwards becomes ulcerated; and the lumen is diminished, or completely choked up by granular *débris*. Frequently both the mucous membrane and the substance of the kidney are affected. It occasionally happens, when one kidney is exclusively affected, that shrinking of the gland takes place; and a putty-like material, rich in cholesterine, or perhaps even calcareous nodules are found, occupying the smooth-walled cavities produced by the disease. Tuberculosis of the ureters, prostate, vesiculae seminales, bladder, and testicle not unfrequently co-exists.

SYMPTOMS.—When tubercle occurs in small nodules it produces no symptoms, and even in the inflammatory form the constitutional symptoms are, in the earlier stages, not very well-marked; but as the disease advances, fever, passing gradually into the hectic type, is developed. The local symptoms may be negative, but there is frequently pain in the affected organ, with tenderness on pressure, and in some cases a tumour may be felt in front, or percussion may reveal an increased area of dulness in one or both renal regions. The secretion may be normal, or even sometimes excessive in quantity, when the disease is not far advanced. It may be acid or alkaline, of fair specific gravity, albuminous, and sometimes bloody. It often contains a puriform material, with *débris* of renal tissue. Sometimes there are masses of cheesy material, which are eminently characteristic, occurring in no other form of disease of the urinary tract. Occasionally the urine becomes suppressed, and symptoms of uræmia precede the fatal termination. Sometimes a tumour may be felt; and on percussion behind, it may be found that the renal dulness is more extensive on one side than the other.

DIAGNOSIS.—The evidences on which we rely in the diagnosis of tubercular disease of the kidney are the presence of pyelitis, combined with those of tubercular disease in other parts, and above all the deposit in the urine of the characteristic fragments of cheesy tissue above described.

PROGNOSIS.—The prognosis is very unfavourable on account both of the local and of the constitutional conditions.

TREATMENT.—The treatment is merely palliative, to relieve pain or uneasiness; and to seek to improve the general health, by administering remedies which are useful in strumous affections.

31. Kidney, Tumour of.—Any enlargement connected with the kidney, which reveals itself on clinical examination, is regarded as a renal tumour. This may be due to mere hypertrophy of the organ, any form of cystic disease; accumulation of any fluid in the renal pelvis, or in the kidney itself, or a solid new-growth, especially malignant disease. For a description of the signs of these several conditions, the reader is referred to their respective headings in this article.

T. GRAINGER STEWART.

KIESTINE (*κῆς*, I am pregnant; and *ιός*, a pellicle).—**SYNON.**: Fr. *Kiestine*; Ger. *Kyestrin*.—This substance was formerly believed to be peculiar to, and always present in, the urine of women in pregnancy, and it was held, therefore, to be significant of that condition.

Recent investigations show that it may be absent all through pregnancy, or present only during certain months, usually from the second to the seventh; that it may be present in the urine of anæmic persons, male as well as female; and therefore that it has not the diagnostic value which was formerly attached to it.

Kiestine is a nitrogenised body allied to caseine; and, according to Dr. Braxton Hicks, the amount deposited from urine containing it can be augmented by the addition of rennet. Chemically and microscopically it is a variable body. Fat, mucus, crystals of the phosphates, infusoria, and granular matter have been found in it. If urine capable of yielding kiestine be set aside in a tall glass, a cloud, apparently of mucus, becomes visible in the middle of it on the second or third day. This soon rises to the top, and an iridescent pellicle is seen forming on the surface. When this has fully formed, it begins to fall through the fluid in the form of flocculi, until the whole is deposited at the bottom in a whitish layer. Another pellicle containing triple phosphates succeeds this, and putrefactive changes proceed.

No reliance can be placed upon the presence of kiestine as a proof of pregnancy.

ALFRED WHITSHIRE.

KINÆSTHESIS (*κίνησις*, I move, and *αἴσθησις*, sensation).—The sense of movement.

In view of the conclusion that the term 'muscular sense' ought to be abolished, as being in several respects misleading, when applied, as it often is (*see* MUSCULAR SENSE) by different writers with totally different significations, partly referring to some and partly to all the impressions which we derive from our moving members, or from movements generally, the writer (*The Brain as an Organ of Mind*, p. 545, and *Appendix*) has proposed to employ the above term as the designation of an important but confessedly complex sense-endowment. He regards it as a form of sense, 'whereby we are made acquainted with the position and movements of our limbs, whereby we judge of "weight" and "resistance," and by means of which the brain also derives much unconscious guidance in the performance of movements generally, but especially in those of the automatic type.' In regard to the various components of this endowment he adds:—"Impressions of various kinds combine for the perfection of this "sense of movement," and in part its cerebral seat or area coincides with that of the sense of touch. There are included under it, as its several components, cutaneous impressions, impressions from muscles and other deep textures of the limbs (such as fascia, tendons, and articular surfaces), all of which yield conscious impressions of different degrees of definiteness; and in addition there

seems to be a highly important set of 'unfelt' impressions, which guide the motor activity of the brain by automatically bringing it into relation with the different degrees of contraction of all muscles that may be in a state of action."

Kinæsthetic centres or mechanisms would, therefore, in accordance with this view, exist in the brain, just as visual or auditory centres also exist. The cerebral seat or locus pertaining to the movement-sense would perhaps be more difficult, though it would otherwise hold much the same relative rank as the several cortical mechanisms for the more special senses.

Diminution of Kinæsthesis.—In certain cerebral and spinal diseases the sense of movement is known to be blunted, or actually abolished, in some parts of the body; and that in regard either to the whole, or only to some of its component impressions. Concerning perversions or exaltations of this endowment, however, we as yet know almost nothing.

Total abolition of the endowment in the limbs, on one side of the body, exists in certain rare cases of hemianæsthesia, where there is also complete loss of tactile sensibility. On the other hand, it is partially impaired in both lower extremities, not unfrequently, in cases of locomotor ataxy; whilst in another class of cases, without coexisting anæsthesia, there would seem to be an absence of the ordinary unconscious impressions emanating from muscles in action, and as a consequence motor defects of an ataxic order, so long as the movements attempted are not guided by sight impressions. Incoordinate movements pertaining to this latter category are decidedly rare, and stand in need of further investigation.

H. CHARLTON BASTIAN.

KIN-COUGH (Dutch, *Kienkhorst*). Also *Chen-cough*. Both of these words are synonymous for whooping cough. *See* WHOOPING COUGH.

KING'S EVIL.—A popular name for scrofula, originating in an idea formerly held that the disease could be cured by the king's touch. *See* SCHOFULA.

KISSINGEN, in Bavaria.—Common salt waters. *See* MINERAL WATERS.

KLEPTOMANIA.—Insanity characterized by an irresistible impulse to steal. *See* INSANITY, Legal; and CRIMINAL RESPONSIBILITY.

KREUZNACH, in Germany.—Common salt waters containing iodine. *See* MINERAL WATERS.

KYPHOSIS (*κνυψις*, bent).—A synonym for angular deformity of the spine. *See* SPINAL DISEASES OF.

LABIO GLOSSO-LARYNGEAL PARALYSIS (*labium*, a lip; *γλῶσσα*, the tongue; and *πάρεσις*, the throat).—There are two forms of this disease, which have to be considered separately, namely, (A) the chronic form, and (B) the acute form. It will be convenient to discuss the chronic form first.

(A) **Chronic Labio-Glosso-Laryngeal Paralysis**.—**SYNON.**: Fr. *Paralyse glosso-labio-laryngée* (Troussau); Gt. *Progressive Bulbar-paralyse* (Wachsmuth).

DEFINITION.—A progressive symmetrical paralysis of the lips and adjacent facial muscles, of the tongue, pharynx, and sometimes also of the larynx; with or without conspicuous wasting; and often associated with muscular atrophy elsewhere.

HISTORY.—First described by Damesnil, in 1857, and by Duchenne in 1860, the disease was made generally known by Troussau's lecture, published in 1863. By the latter writer it was termed 'labio-glosso-laryngeal paralysis.' The awkwardness of the German version of the term led Wachsmuth, in 1864, to designate it 'progressive bulbar paralysis,' and German literature has given wide currency to the term, which is, however, open to the objection that the term 'bulbar paralysis' has been applied to all paralyzes of the nerves arising from the medulla oblongata.

ÆTIOLOGY.—Of the causes of the affection little is known. It is a disease of later life, being almost unknown under forty. Males are affected more frequently than females. The disease, as such, does not appear to be inherited, but in many cases there is a family history of other affections of the central nervous system. Of immediate causes, exposure to cold, mental anxiety, and imperfect nourishment have been supposed to exert an influence in some cases.

ANATOMICAL CHARACTER.—The tissue of the affected muscles is pale; fatty tissue may be in excess, and the muscular fibres often, but not always, present granular degeneration. They are frequently narrowed; whilst the tissue between them may be increased in quantity, and may contain pigmentary products of degeneration. The motor nerve-fibres to the muscles are grey, translucent, and under the microscope, degenerated. Their nuclei of origin in the medulla oblongata are also diseased. The motor cells are shrunken and atrophied, their processes are lost, and the intermediate tissue is degenerated. The hypoglossal nucleus is examined most readily, and the change in it is striking, as well as in the nucleus of the spinal accessory (larynx). The anatomical change which underlies the affection of the lips has not yet been detected. There is some uncertainty of the precise origin of this part of the facial nerve. Guided by Duchenne's clinical observation and conclusion that these fibres, from their affection with those of the hypoglossal, must arise near the nucleus of the latter, Lockhart Clarke believed he had traced them to a group of

cells close to the hypoglossal nucleus. Later researches, especially those of Pierret and Merynert, have rendered this conclusion doubtful. It is certain, however, that a large number of the fibres of the facial descend to the level of the hypoglossal nucleus. They diverge from the middle line, close to which the hypoglossal nucleus is situated, and some at least pass towards the lower part of the column of cells, which, above, gives origin to the motor fibres of the fifth nerve. But the physiological association of the movement of the tongue and lips is most close. We cannot narrow the tongue without contracting the orbicularis. Hence it is certain that the lower facial nucleus and the hypoglossal nucleus, whether contiguous or not, are closely connected; and that this connected part of the facial suffers, in this disease, in the same manner as the hypoglossal. The same fact is almost certain of the motor nucleus of the glosso-pharyngeal. When there is muscular atrophy in the limbs, a corresponding degeneration may be found in the anterior cornua of the spinal cord, often conjoined with sclerosis in the lateral columns, and in the anterior pyramids in the medulla. There is every reason to believe that, in the chronic form, the atrophic changes in the nerve-elements are the primary alteration.

SYMPTOMS.—The symptoms have the distribution indicated by the name given to the disease by Troussau, the affected parts being the lips, tongue, throat, and larynx. They are, so to speak, arranged about the tongue as a centre. It is in this organ that the earliest symptoms commonly present themselves, as a trifling indistinctness of speech, due to an imperfect articulation of those sounds in which the tongue is most concerned—dental and palatine sounds. The tongue can be still protruded, although perhaps not quite so far as normal. The lips then become weak, and sounds in which the lips are concerned are imperfectly articulated. The vowels *o* and *oo*, in the pronunciation of which the orbicularis contracts, cannot be well sounded. The lips are not brought together so perfectly, or separated so promptly, as in health, and the labial explosives, *b* and *p*, become *f*. Whistling is impossible. The lower part of the face loses its expression, the lips are habitually separated, and the saliva cannot be perfectly retained. The difficulty in articulation is soon increased by the weakness of the palate, which ceases to shut off the nasal cavity, so that a nasal resonance accompanies sounds from which it should be absent. The paralysis of the tongue increases until the organ can no longer be protruded. Deglutition becomes impaired, partly (according to Duchenne, wholly) from the weakness of the tongue, but probably in part also from that of the constrictors of the pharynx. The soft palate ultimately hangs motionless, and, during the act of swallowing, does not close the posterior nares, so that liquids regurgitate into the nose. Food is apt to lodge in the upper part of the pharynx, and

crumbs or liquid to get into the larynx. The laryngeal muscles subsequently become weak, and the glottis cannot be closed. Coughing is, therefore, imperfect; air is driven through the larynx, but there is no sudden opening of a previously closed glottis, and hence no explosive cough. In proportion as the glottis is paralysed, phonation is interfered with, but is rarely altogether lost. As the disease progresses the speech becomes almost unintelligible, being reduced to unarticulated vocal sounds. It is to be noted, however, that the habitual articulation is rarely the best possible. Words can be distinctly articulated by a deliberate effort which are scarcely at all articulated in ordinary speech. The saliva can neither be swallowed nor retained within the mouth, and is constantly dribbling over the lower lip, below which the patient has to hold a handkerchief continually. It has been thought that the quantity of saliva is increased, but the evidence of this is insufficient. The condition of the tongue varies much in different cases. In some it is, throughout, large, broad, flabby, and soft to the touch. In others it is conspicuously wasted, and covered with wrinkles and furrows from the shrinking. In some cases the lips retain their normal size, in others they are distinctly thinner than natural. This striking contrast between different cases led Duchenne to distinguish two varieties, the *atrophic* and the *paralytic*. Most later writers have, however, rejected this distinction, on the ground that, *post mortem*, muscular wasting has always been found, whether the tongue was large or shrunken. In the former condition fatty tissue prevents the wasting from being conspicuous during life. There is certainly, however, a marked contrast between the appearance of the tongue in the two cases. In the affected muscles the electrical irritability is usually little changed; they still contract to the faradic current, even when the atrophy is conspicuous. Erb found, however, in one case, indication of the reaction of degeneration, in undue readiness of contraction to the anodal (positive) closure. Other muscles of the head are rarely affected. Those in the upper part of the face always escape. But in many cases muscular atrophy in the limbs, in greater or less degree, is associated, with or without 'contracture.' So, too, in cases of ordinary muscular atrophy, commencing in the limbs, the lips, tongue, and throat are often affected towards the end of the case, in the same manner as in the disease now under consideration. Death, in labio-glossal paralysis, is usually the result of asphyxia, due, in part, to the difficulty in deglutition. Sometimes the patient dies in a paroxysm of coughing, occasioned by an ineffectual attempt to swallow liquids or saliva.

DIAGNOSIS.—Before labio-glossal paralysis was well known, the difficulty in swallowing was ascribed to a chronic inflammation of the fauces, but this mistake is now scarcely possible. The symptoms have to be distinguished from those due to other diseases of the medulla, and to disease elsewhere. Many acute lesions, in the region affected in this disease, may cause similar symptoms, but these are distinguished by their sudden onset. Compression of the medulla may also give rise to symptoms of similar distribution, but these are uncommonly unilateral, and often accompanied

by a preponderant affection of the muscular part of the spinal accessory, and by great weakness, without wasting, in the limbs. Occasionally movements of the tongue are impaired by disease of the cerebral hemispheres. The movements of the tongue are especially represented in the lower part of each ascending frontal convolution. When this is diseased on one side, the loss is soon compensated for by the centre in the opposite hemisphere, but a symmetrical bilateral lesion in this situation may cause complete paralysis of the tongue, as in a case recorded by Dr. Barlow. Such paralysis also is acute in onset.

PROGNOSIS.—The prognosis is most grave. The disease consists in a slow degeneration of the nerve-elements, and although, in some cases, a temporary arrest may be obtained, it is doubtful whether, in any instance of this form, considerable improvement has occurred.

TREATMENT.—The degenerative tendency of chronic labio-glossal-laryngeal paralysis is usually beyond the reach of remedies. Therapeutical efforts must be directed to the endeavour to retard it by nervine tonics, quinine, strychnine, arsenic, nitrate of silver, and the like. The writer is unable to agree with Erb's condemnation of strychnine as harmful in these cases, although he has seen little benefit from its use. Electricity may be tried, although too often it is unsuccessful. Faradisation should be applied to the affected muscles, if they still react to it. Erb strongly recommends the application of the voltaic current through the throat, the positive electrode being placed on the back of the neck, the negative stroked down the side of the pharynx externally and such a strength being employed as shall produce reflex movements of deglutition. Change of air is desirable in the early stage, and rest is imperative. Food must be carefully regulated, easily digestible varieties being reduced to a semi-solid condition. In the later stages, should swallowing be impossible, nourishment must be administered by an œsophageal tube, or, what is better, by a catheter introduced through the nose. Belladonna or atropine may, to some extent, check the troublesome flow of saliva.

(B) *Acute Labio-Glossal-Laryngeal Paralysis.*—**SYNONYMS:** Acute bulbar paralysis; *Myelitis bulbi*.

DEFINITION.—Paralysis of similar distribution to that of the chronic form, with or without conspicuous wasting, of sudden onset, and due to an acute process.

ÆTIOLOGY.—The causes of this affection are for the most part those which lead to acute lesions elsewhere in the brain, especially degeneration of vessels, syphilitic disease, and injuries. It is a disease chiefly of late life.

ANATOMICAL CHARACTERS.—Little is known of the exact condition in cases of acute onset which have recovered with persistent labio-glossal paralysis. In cases which have died rapidly, foci of softening in the medulla have been found; and there is reason to believe that such softening, from vascular occlusion, is the most common cause of the condition. Probably a small hemorrhage may also give rise to it. The symmetry of the symptoms in the acute form, and their

limitation to the parts which are affected in the chronic disease, show the close relation of the central structures, so that they are all affected by the one lesion. The wasting in some of the *curps* of this variety is very much slower than that which follows an acute lesion of motor grey matter elsewhere. It is possible that the ascending fibres from the nuclei concerned may pass up close to the middle line, in a situation in which all may be damaged by a single lesion.

SYMPTOMS.—The onset is sudden, often with headache and giddiness, rarely with loss of consciousness. The patient suddenly finds a difficulty in swallowing and in articulation, with inability to protrude the tongue. Respiratory disturbances—cough, dyspnoea, and hiccough—may be present. There may be convulsions and weakness in the limbs, sometimes with tingling, but very rarely with loss of sensibility. Many cases which present these symptoms die rapidly in the course of a few hours or days. In those which recover, a paralysis of the tongue, lips, throat, and larynx may remain, identical in all respects with that which characterises the chronic form, and there may or may not be conspicuous wasting. The course is, however, not progressive. The patient may remain in the same condition for a considerable time, and even exhibit marked improvement.

DIAGNOSIS.—The diagnosis of the acute form of labio-glossolaryngeal paralysis calls for little remark. It must be remembered that the symptoms may deviate from the type more than in the chronic variety, as the lesion sometimes produces irregular effects. It is chiefly liable to be confounded with the impairment of movements of the palate and tongue sometimes left after double hemiplegia, from which the history suffices to distinguish it, the two attacks of hemiplegia usually occurring at different times. The rare symmetrical affection of the surface-centres for the tongue, mentioned above, is also not simultaneous on the two sides, and it is associated with at least transient hemiplegic weakness.

PROGNOSIS.—If the patient recover from the immediate effects of the lesion, the prognosis of the paralysis of the lips, tongue, and other parts is better than in the chronic form, inasmuch as recovery of slightly damaged structures may lead to a considerable degree of restoration of power. The prognosis is also better if there is any reason to ascribe the mischief to syphilitic disease. Nevertheless, in some acute cases the paralysis remains absolute, although even in these there is not the tendency to increase which is seen in the chronic variety.

TREATMENT.—Any causal indication must be carefully sought for in acute labio-glossolaryngeal paralysis, and treated, especially evidence of syphilis. In other conditions the treatment is that for the lesion which is supposed to exist. Electrical treatment of the muscles is of great importance, in order to prevent, as far as possible, secondary degenerations, which are apt to occur before the partially damaged structures have recovered. The remarks regarding feeding in the chronic form are equally applicable to the acute variety.

W. H. GOWEN.

LACHRYMAL APPARATUS, Diseases of (δακρυμα, a tear).

The lachrymal apparatus consists of the gland, with its excretory ducts; and of the puncta, the canaliculi, the lachrymal sac, and the nasal duct, through which superfluous tears are conveyed into the nose. The diseases of this apparatus are almost limited, with the exception of growths affecting the gland itself (see OBIT, Diseases of), to the excessive secretion of tears, and to impediments to their escape into the nose. To excessive secretion, or to impeded outflow, the common term *epiphora* has been applied; but the great majority of cases of epiphora are due to the latter of the two causes.

Epiphora.—*Excessive secretion of tears* is described by authors as an affection for which it is not always possible to discover an adequate cause, and it may perhaps be sometimes due to the prolonged operation of emotional influences. In most instances, however, it is associated with some kind or degree of conjunctival irritation, and is to be regarded only as a reflex phenomenon hence arising. It is well known that any temporary or accidental irritation, such as may arise from the intrusion of a foreign body into the conjunctival sac, is apt to be followed by a copious secretion of tears, which assist in dislodging the offender; and irritations of a more chronic kind, produced by congestion or irregularity of the lining membrane of the lids, may have a similar effect.

Impediments to the escape of the tears, causing them to collect in the conjunctival sac, or even to flow over the cheek, may depend upon displacement of the puncta, so that these apertures are no longer applied to the conjunctival surface, from which they normally remove superabundant moisture by capillary attraction. Such displacements affect chiefly the punctum of the lower lid, and may be consequent either upon conjunctival swelling, by which the lid is pushed away from the eye, or upon paralysis or weakness of the orbicular muscle, which allows the lid to fall by the action of gravity. In some cases epiphora will depend upon obliteration or occlusion of the puncta. The former condition is incurable; the latter may be produced by plugs of inspissated mucus, which may be removed by the careful employment of a probe.

But the most ordinary cause of obstruction is stricture of the nasal duct, in which condition the tears are arrested a little below the sac, and the sac consequently becomes over-distended. In this condition, the sac can be seen and felt as a small lump, situated just beneath the *tendo oculi*. When pressure is made upon this lump, a fluid, consisting of tears mixed with mucus or less mucus or mucus-pus, will regurgitate into the eye, and the lump itself will disappear. The danger in such cases is that the continued distension of the sac will in time excite inflammation of its lining membrane, leading to the formation of pus, and thus to an opening upon the cheek, producing what is called a *lachrymal fistula*. Such an opening never heals until the duct is again patulous, and it is liable to undergo periodic attacks of unsightly inflammation.

TREATMENT.—In all cases of lachrymal hypersecretion, the first thing to be done is to search

under the lids for any concealed foreign body which may be lurking there. If none be detected, examination must be made for conditions likely to be irritating, and they are to be treated, if they exist, by mild astringent or other suitable local applications. There is probably no medicine which can be said to exert any positive effect in diminishing the amount of the lachrymal secretion.

If the displacement of the lid can be cured by treatment addressed to its causes, the tears will usually return to their accustomed channel. If the displacement be incurable, as happens in some cases of paralysis of the *portio dura*, or of chronic ectropion, the patient may often be relieved by slitting open the canaliculus as far as the caruncle, so as to carry back the aperture to the secretion which it is designed to remove.

The treatment of stricture of the nasal duct can often be only palliative. The patient should acquire the habit of emptying the distended sac by finger-pressure many times a day, and of wiping away the fluid, while, to diminish the irritation of the mucous membrane, a drop of any mild astringent lotion may be applied to the inner corner of the conjunctiva two or three times a day, immediately after such pressure has been made. Perhaps the lotion most generally suitable for this purpose is a solution of acetate of lead in distilled water, of a strength not exceeding three grains to the ounce.

When a radical cure is desired, the canaliculus must be slit up, and the patency of the duct restored by the passage of probes through the stricture. If fistula has already formed, or even if the sac is the seat of an abscess, no other plan is available, but for the necessary details the reader is referred to works on ophthalmic surgery.

R. BRIDENELL CARTER.

LACTATION, Disorders of.—The disorders of lactation are numerous. Sometimes the quantity of the lacteal secretion is excessively small and quite inadequate for the support of the child. At other times it is so abundant that the milk will flow from one nipple as the infant is sucking the other, and when the child is removed from the breast, the secretion continues from both sides. The term *agalactia* is applied to the former, and *galactorrhœa* to the latter condition.

1. *Agalactia* signifies either a total suppression of the mammary secretion, or a very scanty supply. It results generally from anemia.

The treatment should be directed towards improving the health of the patient as much as possible, by a generous diet, and tonics, particularly those containing iron. Certain drugs have been employed as galactagogues, and, it has been said, with benefit. The leaves of the castor-oil plant, boiled, have been used as a local application—the liquid for fomentation, and the leaves as a poultice; and a strong decoction of the same plant has been given as a drink. It is doubtful, however, whether such remedies are efficacious. See *Galactagogue*.

2. *Galactorrhœa* occurs in two forms. In one the composition of the milk is normal, but the quantity excessive; in the other form the in-

crease in the bulk of the secretion is due to a preponderance of the watery part of the fluid.

Remedies employed to reduce the amount of the mammary secretion are termed *galactophyga*, and the chief of these are belladonna and iodo of potassium. Belladonna is employed as an outward application, as well as administered internally. The extract rubbed up with glycerine may be spread on lint, and thus applied to the breasts, or the *emplastrum belladonnæ* may be used. The child should not be put to the breast too frequently. If the excessive secretion continue for any length of time, great emaciation may result; and to this condition the term *mammary diabetes* has been applied. Under such circumstances lactation should be entirely stopped as soon as possible. Strapping the breasts tightly immediately after they have been emptied is of use. Every care must be taken to avoid the formation of a mammary abscess, and if the breasts get hard and knotty a breast-pump should be employed to free the tubes.

3. **Depressed nipples** are generally produced by the pressure of stays. If this condition be observed during pregnancy, periodic attempts should be made to draw the nipples out by means of a glass nipple shield, to which an india-rubber tube and test is attached.

4. **Fissures and excoriations of the nipples** often lead to abscess, and it is said that it may sometimes lead to malignant disease. To avoid the occurrence of these, astringents should be applied to the nipples during pregnancy, in order to harden them. Eucalypti cologne and water, brandy and water, or a weak solution of tannin may be employed for this purpose.

Sometimes an abrasion on the surface forms an ulcer or a crack at some part of the nipple, most frequently at its base, which gives rise to great pain during suckling. The remedies for these cracks are astringent applications, such as tannin, flabide collodion, or a weak solution of nitrate of silver. Care should be taken to sponge these away before the infant is again put to the breast, and a nipple-shield with an india-rubber test will be found of great service.

For abscess and other morbid conditions of the mammary gland supervening during lactation see *REPERT, DISEASES OF, MILK FEVER, AND NIPPLE, DISEASES OF.* CLEMENT GODSON.

LACTEAL VESSELS and GLANDS, Diseases of. See *MESENTERIC GLANDS, DISEASES OF*

LAGOPHTHALMOS (Λαγός, a hare, ὀφθαλμός, the eye).—This term is derived from an old supposition that the hare sleeps with its eyes open, and is applied to a condition in which there is inability to close one or both eyes. Lagophthalmos may be due to paralysis of the orbicularis, in which case it will be attended by falling of the lower lid, and will generally be associated with paralysis of other muscles supplied by the *portio dura* (see *FACIAL PARALYSIS*); to the contraction of cicatrices; to spasm of the upper eyelid (see *THIRD EYE, DISEASES OF*); or possibly to congenital malformation of the lids. In paralytic lagophthalmos, the treatment is that of facial paralysis. Where there is contraction

or deformity, each case must be considered on its own merits, with regard to the possibility of obtaining relief from a surgical operation.

R. BRIDFORD CARTER.

LARDACEOUS DISEASE (*lardum*, bacon) — A synonym for albuminoid disease, which is so called from the resemblance of the cut surface of an affected organ to raw bacon. See ALBUMINOID DISEASE.

LARVALIS (*larva*, a mask). — A term usually associated with porrigo. The thick incrustation which is sometimes seen covering the face of children affected with eczema, and constituting a hideous mask to the features, is an example of *porrigo larvalis*, or rather *eczema larvale*, as likewise is ordinary milk-crust.

LARVATED (*larva*, a mask). — A term applied to certain diseases, when their ordinary characters are masked or concealed, as, for example, typhoid fever. See TYPHOID FEVER.

LARYNGEAL PHTHISIS. — A morbid condition of the larynx, supposed to be of a tubercular nature, and either associated or not with pulmonary phthisis. See LARYNX, Diseases of, and PHTHISIS.

LARYNGISMUS STRIDULUS (*larynx*, the windpipe, *stridor*, a noise) — A form of obstructed breathing, attended with a peculiar stridor or crowing sound during inspiration, and dependent on spasm of the muscles of the glottis. See LARYNX, Diseases of, 9 Spasm.

LARYNGITIS. — Inflammation of the larynx. See LARYNX, Diseases of, 3. Inflammation.

LARYNGOSCOPE. The. (*ἀδρυς*, the larynx, and *σκοπέω*, I look.) — DEFINITION. — An instrument for illuminating the interior of the larynx and trachea, and reflecting those parts so as to present their image to the eye of the observer.

DESCRIPTION. The apparatus for laryngoscopy consist of a small round plane mirror, set on a metal stem and fixed in a wooden handle, for introduction into the throat, and, for concentrating and reflecting the light into the throat, a concave reflector to be worn in front of the forehead, or perforated for wearing in front of the eye of the observer. With this throat-mirror and reflector, any lamp, or even a candle, is available, but brilliant illumination contributes so much to the distinctness of the image that some apparatus to condense the light is also desirable. Either a special apparatus with a bull's-eye lens, or a globe of water, such as a plain round decanter, forms a powerful condenser, and with it the concave reflector may be dispensed with, the light being concentrated directly by the globe of water on the throat of the patient.

APPLICATION. — In practising laryngoscopy, the first object is to throw a brilliant light into the pharynx. Sunlight falling directly, or reflected from an ordinary looking-glass, through the mouth into the throat of the patient; bright daylight, or the concentrated light of a lamp or candle, are each of them available for this purpose.

The patient being placed beside and a little

in front of the lamp, when the reflector is used, or opposite the window, or lamp and concentrator, if direct light is employed, the operator seats himself opposite him, and adjusts the reflector which he is wearing, or the concentrator in front of the lamp, so that when the patient sits upright, with his head inclined slightly back, his mouth widely open, and the tongue put out, the light shall be concentrated on the back of the pharynx and velum palati.

The first object being thus attained, the next is to throw the light into the larynx. While the patient breathes deeply and quietly, his protruded tongue, protected by a napkin or handkerchief to prevent its slipping, is held steadily but gently forward, either by his own hand, or by the disengaged hand of the operator, and the throat-mirror, previously warmed to prevent the condensation of moisture on its surface, held like a pen, is passed into the patient's throat and held with its back steadily pressing against and raising the soft palate and uvula at such an angle that it throws the light into the larynx. This angle will vary according to the position of the patient and the part of the larynx which we wish especially to examine, and the inclination of the mirror must be altered, it must be raised or lowered, brought forward or advanced further in the pharynx, as may be necessary, the operator observing what part is reflected in the mirror, and in moving it being guided by his knowledge of the relation of the various parts of the larynx to each other. Unless the tonsils are enlarged, no part of the fauces or pharynx, except the soft palate and uvula, should be touched, and the operator must be specially careful that the lower edge of the mirror does not come in contact with the back of the pharynx. He must remember also that, while steady pressure can be borne, titillation of any part of the fauces will induce retching. If a patient's nervousness induces retching, or if a spasmodic action of the muscles of the tongue makes it rise, his nervousness must be calmed, he must be induced to take a deep inspiration through the mouth, to accomplish which he will raise the soft palate and depress the tongue, the traction on which must also be slackened. Enlarged tonsils may present an insuperable obstacle to successful examination, in slighter cases either a very large round mirror which presses the tonsils on one side, or a small oval mirror, should then be used. More frequently a pendulous epiglottis hanging back over the upper part of the larynx impedes the view; in such a case the patient must utter, or try to utter, in a high falsetto tone, a prolonged 'eh,' or he must force a laugh or a cough, and the mirror must be held lower in the pharynx, in a more vertical position.

For the topical treatment of laryngeal diseases, in addition to the laryngoscope the practitioner requires a laryngeal probe or sound, brushes on whalebone or stout wire handles, curved at a suitable angle, for applying solutions; a carrier-holder, similarly curved, for applying solid substances; an injector to apply a shower of fluid or spray; and a scarifying instrument. For the operative treatment of polypus, &c., a set of special forceps, a laryngeal écarteur, special knives, and other instruments are necessary;

while, for use by the patient, a spray-producer or atomiser, and a simple inhaler will be required.

THOMAS JAMES WALKER.

LARYNX, Diseases of.—The functions and peculiar anatomical position of the larynx give to its diseases a special importance, and in addition to such objective and subjective symptoms as are common to affections of other organs, we find here modifications of respiration, vocalisation, and deglutition.

The principal diseases and disorders which affect the larynx may be conveniently enumerated and described in the following order.—1. Aphonia, 2. Disorders of circulation, 3. Inflammation; 4. Leprosy, 5. Lupus, 6. Malignant disease; 7. Paralysis, 8. Polypus, 9. Spasm, and 10. Syphilitic disease. See also CHROUP, DIPHTHERIA; and TRACHEA, Diseases of.

1. Aphonia.—SYNON.: Fr. *Aphonie*; Ger. *Stimmlosigkeit*

DEFINITION.—Speaking in a whisper, the sound being produced without closure of the vocal cords.

Various modifications of the note, tone, and quality of the laryngeal voice result from changes in the larynx; and if no air passes through the larynx or mouth, as when a patient breathing through a tracheotomy tube attempts to speak, all sound is abolished, the movements of the lips alone being used in the endeavour to form words. Aphonia is the term applied to the voice produced in the mouth when the laryngeal note is withdrawn from it, and this symptom occurs not only as a result of disease, but as a common functional disorder constituting functional hysterical aphonia. In these cases there is no morbid change in the larynx, no affection of its nerves or muscles. The word *paralysis* should never be applied to this or other similar affections without the prefix *simulated*, the power to exercise the voice exists, but the patient holds it in abeyance. The affection is much more frequent in women than in men. It commonly originates in an attack of catarrh, when, owing to the relaxation and congestion of the laryngeal mucous membrane, vocalisation is inconvenient and requires an effort and the patient whispers to rest his voice, precisely as an exhausted phthisical patient does, even when there is no laryngeal complication. The habit thus originated is maintained for months or years, as long as the unhealthy mental, emotional, and physical condition which we term hysteria lasts; and this may be the only phenomenon of that condition. Like other nervous and hysterical symptoms, nervous aphonia may lead us to suppose the existence of more serious disease; but the patient suffering from nervous aphonia frequently closes the vocal cords in laughing and coughing, while in speaking she never emits even a husky uncertain laryngeal sound. The laryngoscope is of the greatest value for the diagnosis. The interior of the larynx is seen to be free from disease; the vocal cords move during respiration; but when the patient is asked to say *A* or *E*, they remain apart, or are brought together for an instant (showing that there is no loss of power) and again separated and allowed

to remain open, while an apparent effort is made to utter the sound. See VOICE, Disorders of.

TREATMENT.—Well-regulated and interesting employment, or amusement and remedies adapted to the general condition of the patient, must be employed; and the patient must be convinced that she has the power to speak, a power which she does not exercise, usually under the belief that she has it not. The mere expression of a confident opinion, or the promise of a successful result to some system of using the voice may suffice; but usually some measure directed to the part is necessary to induce the patient to exercise her will upon the laryngeal muscles, and to speak, and of those which may be used none is so effective as, or more innocent than electricity, especially when applied to the interior of the larynx. Frequently one application of electricity, particularly when accompanied by the circumstance of a laryngoscopic examination in a dark chamber, makes a sufficiently profound impression on the mind of the patient to restore the voice, the slight pain of the operation occasionally inducing her to exclaim *Oh!* while her attention is diverted from her supposed inability to speak. In using this remedy in these cases, no practitioner can deceive himself into the belief that he is restoring power to a paralysed part; and it is to be regretted that, in describing the treatment of these cases, this belief should be implied, and should have led to a distrust of those who merit the confidence of the public and the profession, from their special skill in the diagnosis and treatment of laryngeal diseases.

2. Larynx, Disorders of Circulation of.—*Anæmia* of the larynx does not exist as a separate disease. Like the pallor of the gums, it is described as one of the symptoms of incipient phthisis.

Congestion of the larynx requires a passing notice. Hyperæmia of some portion of the mucous lining of the larynx results from over-excitation of the voice, exposure to cold, the action of irritants, or any cause obstructing the circulation through the larynx, and it may be consecutive to laryngitis. It causes more or less persistent hoarseness, and a sense of discomfort in the throat; and it excites what is commonly called a 'tickling cough.' The absence of any more serious source of these symptoms is proved by the laryngoscope.

TREATMENT.—Treatment of congestion of the larynx is unnecessary, beyond resting the voice, if the congestion is merely temporary. If more persistent, at the same time that the voice is rested, and attention paid to any general cause of the congestion which may exist, such as disordered digestion, astringents should be applied locally. The larynx may be brushed out daily with a solution of two scruples of sulphate of zinc, or of chloride of aluminum, in the ounce of water, or a solution of nitrate of silver, ten grains to the ounce, may be used, while the patient should inhale three or four times a day the spray of a solution of alum or tannic acid, of a strength of eight grains to the ounce.

3. Larynx, Inflammation of.—The several varieties of laryngitis will be treated of under

the following headings:—(a) *Acute*; (b) *Chronic*; (c) *Tubercular*, (d) *Spasmodic*, (e) *Edematous*

3) *Acute Laryngitis*.—*SYNON*: *Laryngitis catarrhalis*, *Angina catarrhalis*, *Cynanche laryngea*; *Fr. Laryngite aiguë catarrhale*, (*ver Kehlkopfentzündung*).

DEFINITION.—Inflammation of the mucous membrane, or of the mucous lining and subjacent cellular tissue of the larynx; acute in its onset, rapid in its course; disturbing the functions of respiration, vocalisation and deglutition, and accompanied by inflammatory fever.

ÆTIOLOGY.—Like all laryngeal diseases, laryngitis is more common among males than females, and among children than adults. Gout, syphilis, and anything which depresses the constitution, may be regarded as predisposing causes. The most frequent exciting cause is exposure to cold, laryngitis is, indeed, one of the regular sequences of catarrh. It occurs as a complication of exanthematous fevers—in measles, usually of the simple catarrhal or stridulous variety; in scarlatina, of an erysipelatous or oedematous character; in small-pox, variolous pustules being found in the larynx, and in enteric fever and typhus, the consecutive laryngitis being of a destructive type, and leading to rapid ulceration. A very bad form of erysipelatous inflammation of the larynx occurs as a rare complication of erysipelas, and the oedematous variety may result from an extension of diffuse inflammation of the cellular tissue of the neck. Traumatic laryngitis follows scalds, the application of irritants to, and wounds of the larynx.

ANATOMICAL CHARACTERIS—In acute laryngitis the blood-vessels are dilated, the mucous membrane is swollen, and its consistency altered, its cells are infiltrated by the fluid exuded from the blood, and its surface possibly eroded, even in the mildest cases. In the more severe (*parachymatous*) form of laryngitis, the cellular tissue is similarly involved, the exudation is extensive, and the functions of the muscles being seriously interfered with, the movements of the arytenoid cartilages and vocal cords are greatly impeded.

SYMPTOMS.—When laryngitis supervenes on catarrh, the patient feels and shows that there is more serious illness. He is restless and anxious; experiences a feeling of constriction about the rima, complains of sore-throat in swallowing; and points to the larynx as the seat of pain. The breathing is altered, having more or less the characteristics of laryngeal obstruction, namely, the long-drawn hissing inspiration, prolonged expiration of the same character, but with less of the sibilant sound, and diminution or complete abolition of any pause between each respiratory effort. The voice also is altered, becoming husky and uncertain, deeper in tone, and creaking in quality. The patient likewise suffers from cough, of the same character as the voice, from the imperfect closure of the vocal cords it wants sharpness, is husky, and sometimes is accompanied by a hollow, clanging sound, constituting what is commonly called the croupy cough. The expectoration varies according as the inflammation involves the larynx alone, or

extends to the trachea and bronchi. In the former case it is usually clear, thin, tenacious mucus, which is *hawked*, rather than coughed up, mixed with the saliva, which is freely secreted but not swallowed. Sometimes the expectoration contains harder pellets, secreted in the ventricles of the larynx; whilst, if the trachea and bronchi are involved, the usual thick expectoration of bronchitis is also coughed up. Deglutition is painful and difficult, while, on inspection, the throat shows only a little redness, quite inadequate to account for the dysphagia. Accompanying these symptoms there is a rapid pulse, and slight rise of temperature, though the tongue may be moist, and other indications of inflammatory fever slight.

With the laryngoscope the whole interior of the larynx is seen to be of a bright red colour, the vocal cords alone usually retaining their white appearance, but with bright vascular patches, in severer cases the swelling, caused by the infiltration of the mucous membrane and subjacent cellular tissue, is also perceptible.

If the case progress untowardly, the restlessness and anxiety increase, suffocative paroxysms occur, and recur with increasing frequency, the patient's whole attention appears concentrated on the effort of breathing, he dreads to speak or swallow, and if obliged to say anything, he takes first a laboured inspiration, and then with a straining effort, painful to witness, brings out what little voice is left. Gradually, as the tension of the blood becomes more imperfect, drowsiness comes on—the eyes, staring in the previous stage, are half closed by the drooping lids; the face, bathed in perspiration, becomes livid, and death occurs, probably in a paroxysm of suffocative dyspnoea.

COMPLICATIONS AND SEQUELÆ.—The complication of laryngitis with other inflammatory diseases of the respiratory system will be referred to immediately, but there are two symptoms, namely, oedema and spasm, which complicate laryngitis, and by their prominence give a distinctive character to the disease. See *Edematous Laryngitis*.

DIAGNOSIS.—Acute laryngitis, whether simple, stridulous, or oedematous, is apt to be confounded with that form of inflammation which is characterised by the formation of a false membrane in the larynx, namely, croup or laryngeal diphtheria. If practicable, a laryngoscopic examination, showing the absence of false membrane, is the most certain means of diagnosing simple from pseudo-membranous laryngitis; but even where perfect casts of the trachea, bronchi, and primary bronchia were expectorated, the writer has seen the larynx absolutely free from false membrane, and simply inflamed. The absence of diphtheritic membrane in the fauces, of acrid excreting discharge from the nostrils, and of glandular swellings, as well as the mode of accession of the symptoms, would lead us to regard the case as simple laryngitis; while the presence of any of these symptoms, or the prevalence of an epidemic of diphtheria, would lead us to suspect false membrane. Even after due consideration of these points, and of the character of the voice, cough, &c., in certain cases we are unable to say whether we have to deal

with simple, or with pseudo-membranous laryngitis. The stridulous laryngitis or false croup of children is further distinguished from true croup, by the sudden cessation of the symptoms at night; by the *noisy* clanging character of the cough, as distinguished from the *husky*, suppressed, though possibly clanging cough of croup; by the similar absence of hoarseness in the voice, and by the progress of the case, true croup or diphtheria increasing in intensity, while, from the first sudden onset of the symptoms, false croup diminishes, unless complicated with lobular pneumonia or other severe disease. From laryngismus stridulus acute laryngitis is distinguished by the presence of slight pyrexia, and other indications of primary inflammatory affection of the larynx and air-passages; by the absence of indications of any other affection of the nervous system, or of a tendency to convulsions; by the usual occurrence of the attack in the night only; by the slighter affection of the breathing, and by the frequent *croupy* cough, which is the prominent symptom, and which is wanting in laryngismus.

Prognosis.—In mild attacks of laryngitis all the symptoms exist only in a slight degree, and disappear in a few days under simple treatment. Such is the ordinary course of the false croup of children. In adults laryngitis may occur in any degree between the mildest form and that in which, the symptoms being all most intense, it may prove fatal in a day or two, or even in a few hours. The danger depends in great measure on the amount of oedema present, and this on the extent to which the submucous tissue is involved. Those cases which are consecutive to diffuse cellular inflammation of the neck, or to scarlatina or erysipelas, are most unfavourable, so also are those in which there is renal disease. Laryngo-typhus is especially fatal, as is also the oedematous laryngitis resulting from scald in children. Although mild laryngitis usually terminates favourably in a few days, it is necessary that every case should be sedulously watched, as at any period dangerous symptoms may set in and prove rapidly fatal. The disease is most deadly in the young. Acute may pass on to chronic laryngitis, and occasionally, but rarely, may cause chronic ulceration.

Treatment.—As soon as the first indications of even slight laryngitis are observed, the patient should be confined to a warm room, poultices should be applied to his throat; he should inhale the steam of either plain water, or of water containing a few drops of iodine, and small doses of liquor morphis hydrochloratis and liquor ammonie acetatis should be given every three or four hours, 4 or 5 minims of antimonial wine being added if secretion seem deficient. Should the symptoms increase in intensity emetics may be administered, and a blister should be applied on each side of the thyroid cartilage. The diet should be chiefly liquid; and, as a rule, no stimulants are required. Should the dyspnoea become urgent, tracheotomy must be performed; and this may be called for so suddenly, that as soon as a case of laryngitis comes under his care, the practitioner should be ready for the operation. After the trachea has been opened, the patient is to be kept with the same care in a warm

moist atmosphere, a sponge continually changed and wrung out of hot water containing a little tincture of iodine should be kept in front of the tube, and the air should be warmed and moistened as it is drawn through the sponge, which also catches the secretions coughed through the tube. With due care in the performance of the operation and after-treatment of the patient, in cases of simple laryngitis, tracheotomy is almost always successful, but it should not be resorted to unless the case is urgent. Laryngoscopic examination will materially help the practitioner, who may live at a distance from his patient, as to the safety of leaving him without a tube in his throat. Circumstances may lead to the postponement of the operation until the patient is *in extremis*, but even then it should be resorted to. The writer has twice operated upon patients who were believed to have just died, with the effect of restoring them to life for some days, although in neither case was the result ultimately successful, both being cases of diphtheria, which killed the patients, notwithstanding the relief to the laryngeal obstruction.

Simple cases of false croup in children are usually relieved by warm poultices to the throat, or by an emetic, the last remedy being very effectual. Where *oedema* complicates laryngitis, very active treatment is required. In the slighter cases, the spray of a solution of 8 or 10 grains of tannic acid in an ounce of water, or of alum, 10 grains to the ounce or of a saturated solution of chlorate of potash, should be inhaled; if the case is more severe, scarification by a long curved bistoury, with a cutting edge only at the point, will in most instances give relief. If by the laryngoscope the oedema has been proved to be infraglottic, scarification is not practicable. Should the symptoms become urgent, tracheotomy must be performed in such a case, and in any case of oedema, the urgency of the symptoms may decide the practitioner to prefer it to scarification. The treatment of traumatic oedema, the result of scald of the throat, is usually unsatisfactory; it must be surgical, by scarification or tracheotomy. Scarification is sometimes followed by severe hemorrhage, and the surgeon who undertakes either this operation or tracheotomy, must be prepared to meet any emergency that may arise.

(b) **Chronic Laryngitis** — **DEFINITION.** — Low persistent inflammation of the mucous membrane and subjacent tissue of the larynx, occasionally confined to the glandular structures only.

ETIOLOGY.—Specific forms of chronic laryngitis, to be separately considered, result from tubercle, syphilis, &c. The simple form almost always depends on exposure to cold, and the too early and frequent use of the voice, or other want of care, after acute laryngitis; it is also a definite result, according to Cohen and others, of over-feeding. The variety called 'follicular' or 'glandular' laryngitis depends on habitual over-exertion of the voice, not unfrequently coupled with excessive use of alcohol or tobacco; it is a complaint of public speakers and singers.

ANATOMICAL CHARACTERS.—The mucous membrane of the larynx is swollen and hyperæmic; the vessels are dilated, usually in patches; the

vocal cords are usually least affected, though they may present streaks of congestion, ulceration is rare in simple chronic laryngitis, but there may be abrasions of the surface. In glandular or follicular laryngitis, sometimes called 'clergyman's sore-throat,' the mucous membrane generally is but little thickened; but in the parts richest in glands, that is over the arytenoid cartilages, at the base of the epiglottis and parts of the ventricular bands, the racemose glands are hypertrophied, the surrounding vessels dilated, the ducts and cul-de-sacs enlarged, and their orifices closed, so that the secretions accumulate and sometimes escape by ulceration. Usually a similar condition of the follicles of the pharynx accompanies this form of chronic laryngitis.

SYMPTOMS.—The symptoms of chronic laryngitis are hoarseness and aphonia after slight exertion of the voice, a hacking cough, with but little of the brassy, laryngeal character, either no expectoration, or only a little tenacious mucus, a sense of dryness, with slight pain in the throat; and occasionally dyspnoea on unusual exertion.

COMPLICATIONS AND SEQUELÆ.—Very rarely ulceration may take place, or a sudden accession of acute symptoms with œdema may occur, and this may be followed by suppuration and necrosis of the cartilages.

DIAGNOSIS.—In cases of chronic disease of the larynx a laryngoscopic examination is almost always practicable, without the laryngoscope, diagnosis and treatment can be only guess-work, with it the appearances described above are clearly recognised.

PROGNOSIS.—Chronic catarrhal laryngitis may subside spontaneously, but is usually persistent unless properly treated. It may lead to permanent hypertrophy of the mucous membrane and thickening of the cellular tissue, and this may be general, or limited so as to resemble a tumour. It sometimes gives rise to warty growths. Glandular laryngitis is very obstinate. Neither form of non-specific chronic laryngitis is in itself dangerous to life.

TREATMENT.—Any imprudence in diet or hygiene must be corrected, and the voice rested as much as possible. About every other day the larynx should be brushed out with a solution of nitrate of silver, 40 grains to the ounce of water, and the spray of a solution of tannic acid and alum, or the steam of boiling water containing a drachm of tincture of iodine, or about 10 drops of fir-wood oil, dissolved in spirit, in the pint of water, should be inhaled three or four times a day. In obstinate cases, inhalations of the turbinthinate balsams, mixed with two or three times their bulk of ether, as recommended by Dr Symonds, may be used, the warmth of the hand being sufficient to volatilise such solutions prepared according to his formula. Attention must be paid to the general health, and to the state of the digestive organs.

(c) **Tubercular Laryngitis**—**SYNON.**: Laryngeal Phthisis; *Fr. Phthisis Laryngis*; *Ger. Kehlkopf-Tuberculose*.

DEFINITION.—A specific inflammation of the larynx, depending on the presence of tubercle,

accompanying, and sometimes preceding, tubercle of the lungs, and leading to destructive ulceration of the soft parts, and to caries and necrosis of the cartilages of the larynx.

ETIOLOGY.—Pulmonary consumption may be complicated by simple laryngitis, but the disease specified above is itself tuberculous, its predisposing causes being those which favour the development of tubercle in persons of scrofulous constitution, and the exciting causes the same as those of simple laryngitis.

ANATOMICAL CHARACTERS.—The majority of pathologists are agreed that, even in the earliest stages of tubercular laryngitis, minute deposits of milary tubercle will be found, and these may generally be seen causing slight eminences, differing from the follicles in glandular laryngitis, in that from the first they become centres of ulceration of the mucous membrane. This destructive process extends to the deeper parts, involving the fibrous tissues; the articulations suppurate, and the ligaments and cartilages are destroyed, and prominent granulations and fungous growths occasionally spring from the ulcers near the vocal cords. The epiglottis is usually the first cartilage attacked, then the arytenoids and the cricoid, the last being the most liable to necrosis. Occasionally abscesses form, the necrosed cartilages being included in them, and ultimately every tissue of the larynx becomes involved.

SYMPTOMS.—In tubercular laryngitis the symptoms specially dependent on the condition of the larynx are hoarseness and weakness of the voice; cough, at first frequent and tickling, later husky, laboured, and ineffectual; difficulty in swallowing, often distressing, from the early affection of the epiglottis and upper parts of the larynx, expectoration, varying according to the extent to which the lungs are affected, and sometimes, in the later stages, including portions of cartilage, little difficulty of breathing at first, but later, from œdema, spasm, or great destruction of tissue, urgent dyspnoea, which may necessitate tracheotomy. To these symptoms, sooner or later, are usually added those of advancing pulmonary phthisis. A pale œdematous condition of the aryepiglottidean folds is usually the first indication of laryngeal phthisis observed with the laryngoscope; then swelling and ulceration of the epiglottis, followed by ulcers about the arytenoid cartilages. The view of the disease, as it extends lower, is usually prevented by the secretions, and the swollen condition of the epiglottis and upper parts of the larynx.

COMPLICATIONS AND SEQUELÆ.—These have been sufficiently indicated in the description of the pathology and symptoms of the disease.

DIAGNOSIS.—Tubercular must be diagnosed from simple chronic laryngitis by the early occurrence of œdema and ulceration; and from acute œdema by the mode of onset of the symptoms. From syphilitic disease the diagnosis is more difficult; there is no distinction in the appearance of the ulcers, but in syphilis there is less œdema, and the ulcers may heal, and present cicatrices. The detection of tubercle in the lungs, or other indications of the tubercular diathesis, will help to determine our opinion.

PROGNOSIS.—Tubercular laryngitis is never

cured; but the rapidity of its progress may sometimes be checked. If it precedes the deposit of tubercle in the lungs it may last in its early stage for years: if it supervenes on pulmonary consumption the downward progress is very rapid.

TREATMENT.—This must have reference to the diathesis on which the disease depends, and to its local manifestation. The constitutional treatment is fully discussed in the articles *PHthisis*, and *SCROFULA*. The local treatment must be directed to mitigate the severe pain, and if possible to the cure of the disease. Rest must be obtained for the vocal organs, whilst the food should be such as to cause little inconvenience or pain in swallowing. Artificial feeding by enemata or even by the œsophagus tube may be needed. Soothing applications include ice and iced water; demulcent gargles (*see* *CLARULEN*); the insufflation of a powder composed of one grain of starch to 1-6th grain or more of morphia, or the application by the brush of a mixture of bismuth, gum, and 1-6th grain of morphia. Soothing inhalations of conium, benzoin, chloroform, or hops may also be used (*see* *INHALATIONS*). Occasionally, to promote the healing of ulcers, mild solutions of perchloride of iron, nitrate of silver, or sulphate of copper, may be tried. A leech or two over the larynx, followed by a poultice, may prove useful in some cases.

(d) **Spasmodic Laryngitis** - *SYNON* False Croup; *Croup*. *Fr. Laryngite ou Angine stridulense*; *Ger. Pseudo-croup*.

DEFINITION.—A mild degree of inflammation of the larynx and air-passages, occurring chiefly in young children; accompanied by attacks of laryngeal spasmodic cough and breathing, which come on usually at night, and commonly terminating favourably in a few days.

Spasm of the glottis occurs as a purely nervous affection, as in laryngismus stridulus, but the complaint defined above is a variety of laryngitis; it is one about which practitioners are continually consulted, and is what mothers mean when they talk of a child being liable to croup.

ÆTIOLOGY.—Any of the ordinary causes of catarrh will, in a child with a tendency to this affection, induce an attack. The age of the child is material in producing this tendency, as is also family proclivity; false croup occurring usually in children of from two to six or seven years old. It occasionally complicates the eruptive fevers, and especially measles.

SYMPTOMS AND TREATMENT.—A child, having previously shown signs of catarrh or slight bronchitis, and having probably been a little hoarse, wakes up suddenly from sleep with a clanging, spasmodic, not husky, cough, and with dyspnoea, characterised by the coking sound with each inspiration which indicates spasmodic closing of the larynx, or by a complete spasm with convulsive movements of inspiration, lasting for a few seconds. The voice is not affected, or if altered it is not husky, but is simply emitted with difficulty, from the difficulty in regulating the action of the vocal cords. There is not more pyrexia than generally accompanies a severe cold. Under simple treatment the attack usually sub-

sides, and the child drops asleep. The attack may be repeated on one or two following nights; but the first is usually the most violent, and that which most alarms the little patient and those around him. These are the symptoms of an ordinary attack of false croup, but its essential cause being some degree of inflammation of the air-passages, it is clear that this may go on to a severer form, and the child, first attended for false croup, may die from pneumonia or other inflammatory affection of the respiratory system, the symptoms produced by the severer affection of the lung combining with and complicating those dependent on the larynx. The persistent dyspnoea, and other symptoms, must in such a case be traced by the practitioner to their proper sources, or he may erroneously suspect and adopt treatment for graver laryngeal disease than actually exists.

(e) **Œdematous Laryngitis** - *SYNON*: *Œdema glottidis*, *Œdema of the Larynx*; *Fr. Laryngite œdémateuse*, *Ger. Kehlkopfœdem.*

DEFINITION.—Inflammatory exudation into the submucous areolar tissue of the larynx, of serous, sero-purulent, or sero glutinous fluid.

The exudation usually attacks first the ary-epiglottic folds and the epiglottis, and it may extend thence to the ventricles and other parts of the larynx, the vocal cords themselves being seldom affected. The submucous tissue below the vocal cords, lining the cricoid cartilage, may be the sole seat of the exudation; a form of œdema which has been attributed usually to a gouty constitution. Whether occurring in the course of acute laryngitis, or, as is more frequently the case, supervening on chronic laryngitis, œdema of the larynx is of the greatest importance, being least fatal when an accident of chronic disease. Œdema complicates laryngitis of an asthenic type, such as cases consecutive to the exanthemata, and is always present in the cases due to scalds from drinking boiling fluids. It is this form of laryngitis which occurs in persons labouring under Bright's disease, the œdema in these cases not being passive dropsy, but the result of inflammation.

ANATOMICAL CHARACTERS.—The mucous membrane in œdematous laryngitis is rather attenuated than thickened, and but little injected, unless it occurs as a complication of the superficial form of inflammation. Especially in scalds there is but little hyperæmia, but there is death and vesication of the mucous membrane with excessive œdema.

SYMPTOMS.—The symptoms indicative of laryngitis exist in an increased degree when this is complicated with œdema, the swelling of the epiglottis interfering especially with deglutition, and that of the aryepiglottic and ventricular bands causing very dangerous dyspnoea. By examination with the finger, and far better by the laryngoscope, we observe further the physical condition caused by the swelling. The epiglottis is felt, or seen, misshapen, rounded like a chestnut, or its two sides swollen so as to resemble two mucous bladders pressed together in the middle line, and, unless this hides the rest of the larynx, the aryepiglottic folds will be recognised as two long rounded swellings, passing

from before back, and nearly meeting in the centre, the swollen ventricular bands being visible only when there is little œdema above.

TREATMENT.—The treatment of œdematous laryngitis has already been described under the head of acute laryngitis.

1. Larynx, Lepra of.—**DEFINITION.** A specific affection of the larynx, met with only in cases of lepra of long standing, and associated with a similar affection of the buccal mucous membrane, the tongue, and the palate.

ÆTIOLOGY.—The causes are identical with those of lepra in other situations.

ANATOMICAL CHARACTERS.—The disease spreads from the mouth to the epiglottis, which becomes thickened, and is fixed from the infiltration of its mucous membrane. Other parts of the larynx afterwards present the same anatomical changes. The tubercles may ulcerate and cicatrize.

SYMPTOMS, COMPLICATIONS, AND DIAGNOSIS.

The symptoms of laryngeal lepra are those of chronic inflammation, and if the tubercles ulcerate, the ulceration is very slow, and not of the destructive character of syphilis. As lepra of the larynx occurs only when the disease of the skin has been long established, its diagnosis is clear. It usually exists for a long time, even years, before it ulcerates, and even after this it is very slow in its progress, and not fatal.

TREATMENT.—As in other forms of lepra, treatment is almost useless, the fissures and ulcers are said to be relieved by touching with solid lunar caustic. See *LEPRA*.

5. Larynx, Lupus of.—**DEFINITION.** A rare specific form of inflammation and ulceration of the mucous membrane of the larynx, always associated with lupus of the skin.

ÆTIOLOGY.—The causes of this disease, and of lupus of the skin, are identical.

ANATOMICAL CHARACTERS.—In lupus of the larynx great numbers of small red round papules are first formed. These become abraded, and the abrasions gradually form ulcers, which penetrate deeply into the substance of the epiglottis, being triangular in form, with the apex directed forwards. Similar ulcers are found at a later stage in other parts of the larynx.

SYMPTOMS, COMPLICATIONS, AND DIAGNOSIS.—

The symptoms of lupus of the larynx are those of chronic inflammation, but there appears to be no tendency to œdema or to those affections of the cartilages which occur in syphilitic and tubercular laryngitis, from which the disease is further distinguished by the peculiar form of the ulcers and the papules, and the presence of lupus of the skin. It lasts for many years.

TREATMENT.—Lupus of the larynx must be treated locally by caustics or the galvanic cautery; and constitutionally in the same way as other forms of lupus. See *LUPUS*.

6 Larynx, Malignant Disease of.—The larynx is rarely the primary seat of cancer (except in the form of epithelioma), although it is frequently involved by the spread of the disease from the œsophagus, pharynx, and neighbouring parts. The disease occurs usually as a general infiltration of the tissues, and does not form a

polypoid tumour. It gives rise to symptoms of dysphagia, and of laryngeal obstruction, added to those of malignant disease in other situations. The symptoms only occur when the larynx is either attacked primarily, or invaded secondarily, by the disease, mere mechanical pressure by growths external to it not interfering with its functions, although they may displace the organ to a very great extent.

TREATMENT.—The obstruction to respiration may demand the performance of tracheotomy; and if the lower part of the trachea is free from disease, the operation will prolong life. If the trachea itself is extensively affected, the insertion of the tube may increase rather than relieve the dyspnoea. Removal of a cancerous larynx was first practised by Billroth, and has since been performed by several Continental surgeons. The results of the operation have, however, been so unfavourable that it cannot be recommended in this form of disease.

7 Larynx, Paralysis of. **DEFINITION:** Loss of power in the laryngeal muscles, occurring in connection with disease or poisoning of the nervous centres, or with pressure upon or disease of the laryngeal nerves, caused by aneurism, enlarged venous or bronchial glands, or other intrathoracic tumours.

VARIETIES AND TREATMENT.—The commonest effect of disease or of pressure upon the recurrent laryngeal or motor nerve of the larynx is paralysis of the abductors, causing the vocal cords to approximate in the middle line, in a relaxed state. They are not tense even when an attempt is made to speak; and during respiration a narrow chink is left, with relaxed edges, causing very stridulous breathing and, possibly, fatal asphyxia. Paralysis of the abductors, unilateral or bilateral, when one or both vocal cords are seen at all times relaxed and drawn aside, is a consequence of disease of the superior laryngeal nerve, which supplies the cricothyroid and arytenoid muscles. These varieties of paralysis are readily recognised by the laryngoscope, and they usually cause aphonia, without necessarily dyspnoea. When these cases are of long standing the muscles become atrophied as in other paralysed parts. The condition usually depending on serious disease without the larynx, treatment can be of little avail. Tracheotomy may be called for to avert asphyxia. Cases are recorded where the local use of electricity has cured paralysis, but these were probably cases like those previously described, where paralysis of the abductors is simulated. See 1. *Aphonia*; 2. *PNEUMOGASTRIC NERVE, Diseases of*, and *APPENDIX*.

8 Larynx, Polypus of.—**SYNON.**: Growths of the Larynx; Fr. *Tumeurs, Kydes*, et *Polypes du Larynx*; Ger. *Kehlkopfpolypen*.

DEFINITION.—A morbid growth attached to the walls of the larynx, and projecting into its cavity, in the form of a tumour.

ÆTIOLOGY.—The invention and use of the laryngoscope, leading to accurate diagnosis, has established the fact that tumours of the larynx are of much more frequent occurrence than was formerly supposed. They are most common in adult males who habitually over-exert the voice;

but they occur in either sex, and at any age, from infancy upwards. Inflammatory attacks, syphilis, and anything leading to habitual congestion of the larynx, favour their development.

ANATOMICAL CHARACTERS.—Growths of various kinds occur in the larynx. (a) *Papilloma*, or warty growth, having a base of connective tissue, and coated with epithelium, may occur either as a solitary separate filament, or a group of filaments, or as an agglomeration of little rounded eminences, the whole forming a perfectly defined tumour. It is frequently multiple, increases rapidly; has a tendency to recur when removed; and is of friable texture. It is most common at the anterior commissure of the vocal cords, but these growths may be attached all over the larynx.

(b) *Fibroma* is usually solitary, its size varying from that of a grape-seed to that of a pigeon's egg or more, either sessile or pedunculated, with a bright smooth surface, becoming lobulated as the tumour increases.

(c) *Mixed fibrous and fibro-cellular tumours, sarcoma*, and mixed *lipoma* and *fibroma*, externally resemble fibroma, their nature not being recognisable until after removal.

(d) *Adenoma*, or glandular tumour, is described by Turck as distinguishable from fibroma by its swelling, and altering in colour. It increases rapidly, and is of a dark pink colour at first, becoming whitish as it increases.

(e) *Myxoma*, or mucous polypus, is rare. It presents a smooth, moist-looking, semi-transparent, rounded surface, and, according to Bräns, consists of a shiny matrix, with intersecting fibrillæ, inclosed in the altered mucous membrane.

(f) *Cystic polypus* is usually the result of a change in some other tumour. It may, however, occur as a primary growth; and a case is recorded where such a growth caused the death of an infant, thirty-six hours after birth.

(g) *Epithelioma* is not uncommon, presenting the usual structure and appearance of epithelioma elsewhere.

SYMPTOMS.—Polypus may cause absolutely no inconvenience. The most constant symptom is a modification of the voice. It usually excites dry cough, often spasmodic and croupy. The breathing is but little affected until the growth attains some size, when dyspnoea will set in, at first only on exertion, occasionally spasmodic, as the growth increases, it becomes constant, and at last fatal if the disease is unrelieved. Tumours attached below the vocal cords are rare; when they exist, and are large enough to interfere with the breathing, expiration is as noisy and difficult as inspiration. These growths are usually painless; they may be so situated as to interfere with swallowing, but this is not usual. In addition to these symptoms, the growth can be seen with the aid of the laryngoscope, and felt with the laryngeal probe or sound, and sometimes with the finger. Occasionally portions of a papilloma are expelled by coughing.

DIAGNOSIS.—A certain diagnosis can only be arrived at by a physical examination, unless, indeed, portions of the growth are expectorated. Most forms of growth may be diagnosed by their appearance in the laryngoscope. The point and

extent of attachment may be determined by the skilful use of a laryngeal sound or probe.

PROGNOSIS.—The importance of these growths varies with their situation and rate of increase. A few months have sufficed for the growth of tumours, from their origin to their attaining a size sufficient to threaten suffocation; in other cases they may exist for years without giving rise to any symptom beyond dysphonia or aphonia. As soon as a polypus causes dyspnoea, it has become dangerous. Although a polypus under observation for some time has been seen to grow smaller, and cases occasionally occur where the more friable variety is spontaneously expelled, the disease must practically be regarded as incurable, except by operation or other local treatment.

TREATMENT.—A small stationary fibroma or other tumour, giving rise to but little inconvenience, requires no treatment. Small papilliform growths are amenable to treatment by strong caustic solutions. Almost all other tumours must be removed by operation. Removal may be effected by instruments introduced into the larynx from above with the aid of the laryngoscope, or, where the disease is very extensive, an artificial opening into the larynx (thyrotomy or division of both thyroid and cricoid) may be necessary, the growth or growths being removed through this opening. If the growth is removed *per vias naturales*, it may be crushed through at its base by a properly constructed crusher, it may be seized and torn off by forceps, or it may be cut off by knives or scissors. The particular operation, and the instruments to be used, must be determined by the circumstances of the case. Tracheotomy may be necessary as a palliative measure, where, for some reason, a curative operation cannot be adopted, or it may be required as a preliminary to the radical operation. Where the choice lies between tracheotomy and an operation for removal of the tumour, the latter must always be selected. Removal of the larynx for recurrent sarcoma has been successfully practised in this country by the late Dr. Foulie, and the operation is available where milder measures for the cure of these growths prove ineffectual. After extirpation the voice can be restored by the insertion of an artificial glottis.

9. Larynx, Spasm of.—In the description of other diseases of the larynx, this has been referred to as a frequent and often fatal complication. Spasm is a most urgent symptom when the larynx is irritated by the lodgment of a foreign body or other irritant. It may result from pressure on, or disease of the pneumogastric nerve, from hysteria; and as a manifestation of a more general affection of the nervous system, in which case it constitutes the following special malady.

Laryngismus stridulus.—SWEN: Child-crowing; Spasmodic croup; False croup, Fr. *Spasme de la glotte*; Pseudo-croup nervosus; Ger. *Kehlkrampf*.

DEFINITION.—Short or more prolonged accessions of suffocation; depending on tonic spasm of the adductor muscles of the larynx, and usually of the diaphragm and other respiratory muscles; causing closure of the glottis, and a sudden arrest

of inspiration; and ending in a shrill crowing sound, as the inspiratory act is resumed and concluded. It is unaccompanied by any inflammatory affection of the larynx or air-passages; and is often associated with other convulsive affections.

ÆTIOLOGY.—Anything causing excessive reflex irritability, rachitis, chronic hydrocephalus, and other organic affections of the brain or medulla oblongata, predispose to this convulsive affection. It is undoubtedly sometimes associated with chronic enlargement of the thymus, and with the irritation of teething. A sudden fright, irritation of the larynx by the accidental entrance of food, or some slight agitation as that caused by a child being tossed in the air, may excite the attack.

ANATOMICAL CHARACTER.—This is purely a nervous disease, and there is no anatomical change in the larynx.

SYMPTOMS.—With or without premonitory indications of a tendency to convulsive affection, such as drawing in of the thumbs and great toes, or clenching of the hands; often during sleep, and with no evident exciting cause, or at any time in the day; a child is suddenly attacked with difficult breathing, inspiration being accompanied by the crowing sound characteristic of laryngeal spasm. This may continue for some time, and then gradually subside. The spasm may be short, or it may be longer and more intense, inspiration being proportionately difficult. It may be complete, and the act of inspiration cease entirely, until just as death seems imminent, the spasm relaxes, and with a crowing inspiration breathing is re-established. In the worst cases, and sometimes in the first attack, death does actually occur.

DIAGNOSIS.—The diagnosis of this disease from stridulous laryngitis or real false croup, with which it is in this country frequently confounded, and that even by recent authors, is considered under 3. a, Acute Laryngitis. The symptoms caused by a foreign body lodged in the larynx closely simulate laryngismus stridulus. The nature of the case is decided by its history; and, unless the age of the patient precludes it, by a laryngoscopic examination.

PROGNOSIS.—The milder forms of this malady yield to suitable treatment, and disappear as improvement takes place in the condition inducing the attack. Severe forms, if not fatal in a first, may be so in a subsequent attack. When the spasm depends on some incurable organic change in the nervous system, the case is of course hopeless from the first.

TREATMENT.—Attention to the diet and general management of the child, regular bathing, and the administration of remedies suitable to correct faults of digestion, are necessary. The persevering use of bromide of potassium has been found beneficial by the writer, and chloral hydrate is of undoubted value. For the immediate treatment of the spasmodic attack, prompt immersion in a warm bath, the administration of an emetic, or the use of an anæsthetic vapour may be resorted to; and should breathing not be re-established as the spasm ceases, dashing cold water on the face and chest, friction, application of strong ammonia, and vinegar to the

nostrils, and especially artificial respiration, must be adopted, with the object of restoring the function. Tracheotomy may be requisite, but the practitioner is, unfortunately, seldom present when the indications for the operation arise.

10 Larynx, Syphilitic Disease of.—Syphilis affects the larynx differently according to the stage of the disease at which the organ is attacked. Erythematous maculae, raised mucous patches or condylomata, and superficial ulceration, like that seen in the fauces and pharynx, may occur as secondary symptoms; but the larynx is more commonly and more seriously affected in advanced stages of syphilis. It may then be the seat of small tubercles, varying from the size of a millet-seed to that of a pea, or ulceration may occur, following upon an eruption or upon gummata. The ulcers are usually multiple, deep, and sharp-edged, presenting much the appearance of tubercular ulcers, and the cartilages are frequently necrosed. Sometimes the disease begins with perichondritis, leading to suppuration and subsequent caries and necrosis of the cartilages, external fistule occasionally communicating with the diseased larynx.

SYMPTOMS.—Secondary syphilitic affections cause hoarseness and sometimes loss of voice, with some harshness of breathing, but there is usually neither pain, cough, fever, nor much dyspnoea. The more serious tertiary affections may give rise to all the symptoms caused by tubercular ulceration, but the constitutional symptoms are those of syphilis, as distinguished from consumption.

COMPLICATIONS AND SEQUELÆ.—Although amenable to treatment, and therefore curable, syphilis is more liable than any other affection of the larynx to leave serious consequences. Not only are the cicatrices of the healing ulcers liable to contract the opening of the larynx, and to cause adhesions which may permanently obstruct respiration, but the specific deposits occasionally occur in such a form, that even without ulceration, they produce stenosis or contraction of the larynx or trachea. Tumours of the larynx appear sometimes to result indirectly from syphilis, and, as just mentioned, aërial fistule may be left after necrosis of the cartilages.

DIAGNOSIS.—The secondary affections of the larynx are easily recognised in the laryngoscope, and there are usually other indications of the constitutional taint. Syphilitic must be distinguished from tuberculous ulceration by the concomitant symptoms of the disease, the presence of gummatous tumours, and the occurrence of cicatrization of the ulcers, the œdema and general thickening are also less than in tubercle. From ulcerated epithelioma it may be distinguished by the history; by the fact that the canceroid growths usually extend from the pharynx and œsophagus to the larynx, by the canceroid ulcer being solitary, while syphilitic ulcers are usually multiple; and by the appearance of the sores and their base. Frequently in these cases the amount of secretion prevents a satisfactory view of the parts, and our diagnosis must then be arrived at without the aid of the laryngoscope.

PROGNOSIS.—The prognosis in cases of larynx

grel syphilis must vary according to its form, but unless the case is complicated by some other vice in the system, we may hope to cure it by appropriate treatment. If left to itself, the tertiary form of the disease will probably ultimately destroy the patient. Where it occurs in a person of scrofulous constitution, the prognosis will be less favourable; and if to this be added abuse of alcohol, and irregular living, the chances of recovery are small. At any period of this, as of other laryngeal disease, sudden urgent symptoms are liable to arise, resulting in a fatal termination, a consideration which must induce us always to give a guarded opinion.

TREATMENT.—Local treatment is seldom necessary for the secondary syphilitic affections of the larynx, and we must trust to mercurial inunction and other constitutional remedies. Should a mucous condyloma, from its situation, affect the voice or breathing in a very grave degree, a solution of bichloride of mercury, one grain dissolved in a drachm of weak spirit, may be carefully applied with a brush. Syphilitic ulceration of the larynx requires persevering treatment by iodide of potassium; and where it does not yield to this remedy, appropriately combined with quinine, cod-liver oil, &c., mercury must be employed, the best method being by mercurial inunction, or the hypodermic injection of the bichloride. A prolonged course of the drug being necessary, the patient must pay great attention to his mouth, sucking alum frequently, so as to avoid ptyalism. The local application of a solution of 10 grains of sulphate of copper to the ounce, and touching isolated ulcers with solid nitrate of silver or sulphate of copper, will be beneficial, astringent sedative, or other medicated, and especially iodine, inhalations should also be employed. In old cases of syphilis, warty growths are sometimes seen in the larynx, which may be cured by frequent topical applications, combined with constitutional treatment. When the dyspnoea is dangerous, tracheotomy must not be delayed. It will usually prove successful, although the destruction of tissue and cicatrization may be such as to necessitate the permanent wearing of the tube. Operations for the division of cicatricial bands and adhesions may be required. They should be undertaken only by a skilful and practised laryngeal operator. Two or three cases have been operated upon successfully, where the vocal cords were united in their whole length by a web of adhesions. Heine has removed the larynx for stenosis resulting from syphilis; but extirpation must not be adopted where tracheotomy is available.

THOMAS JAMES WALKER.

LATENT (*latens*, I lie hid).—This word is applied to cases of certain diseases in which their usual characteristic features are obscured and concealed; for example, *latent pleurisy*, *latent scurvy*. Symptoms are also said to be latent when they do not occur under circumstances in which they ought to appear. For instance, cough may be latent in certain cases of phthisis.

LEAD, Poisoning by.—**SYNON.**: Plumbism; *fr.* Intoxication saturnine; *Ger.* Bleivergiftung.

Pure metallic lead has probably no injurious action on the system, but owing to the ease with which it oxidises and forms salts, all of which are poisonous, lead-poisoning is of common occurrence amongst all persons whose occupation brings them much in contact with metallic lead and its alloys, among those engaged in industries in which lead-salts are manufactured, or largely employed, as well as from contamination, accidental or otherwise, of articles of food, drink, or luxury, with lead or its compounds.

Acute poisoning with lead is not common, nor are any of the lead salts actively poisonous. The acetate or sugar of lead is popularly believed to be a virulent poison, but it is by no means so. There are very few fatal cases on record, even from swallowing quantities amounting to an ounce of the acetate or its equivalent. The symptoms are in the main those of irritant poisoning, the chief difference being that constipation is the rule, and diarrhoea the exception.

The *chronic* form of poisoning by lead is of infinitely more importance and prevalence. The sources of it are extremely numerous and varied, and it is almost impossible to specify all individually. The following are among the chief, classified according to the primary form of the poison.

1 **Metallic Lead, Poisoning by.**—Lead-poisoning occurs among lead-miners, metallurgists, and workers in lead or its alloys, such as plumbers, solderers, type-founders, compositors, and manufacturers of lead toys (toy-soldiers). It has been observed also among fishmongers, from using lead counters; in pot-boys, as the result of packing articles of food or luxury in lead-foil; and from contamination of articles of drink by shot used for cleaning bottles, siphon soda-water bottles &c.

Under this head may also be included the very frequent contamination of *drinking water* by lead pipes and cisterns. Pure water, freed from gases and excluded from contact with air, does not act upon lead, but in presence of air the lead becomes speedily acted on, and the water contaminated. An oxide of lead is formed, which being partially soluble in water, allows the action to go on. From its solution the oxide is in great measure precipitated by carbonic acid, which is absorbed. The lead falls as an oxycarbonate, though the presence of carbonic acid in the water keeps a certain quantity in solution. The purer the water the more rapid the action. The presence of certain salts in the water considerably modifies its action on lead. Thus the nitrates, nitrites, and chlorides, by forming soluble compounds with lead, increase the solvent action of the water; and as these salts usually result from sewage-contamination, such water is rendered still more dangerous by passing through lead pipes. Other salts, usually found in spring and river waters, act as protectives by forming insoluble lead-compounds, which being deposited as a crust in the interior of the pipe or cistern, prevent further action. Of this class are the sulphates, phosphates, and carbonates. Hence waters, unless containing much less than the average proportion of lime-salts, after a time cease to be contaminated to any great extent, though the presence of carbonic acid in the water

renders a solution of the crust possible in some measure. Waters so deficient in lime-salts as the Loch Katrine water supplied to Glasgow cannot safely be conveyed in lead pipes. Galvanised iron, earthenware, or slate may in many cases be advantageously substituted for lead, if not possible in all. Lead covers to cisterns are very objectionable, as the water which rises by evaporation condenses and drops back contaminated. The electrolytic action of solders also helps to contaminate water with lead.

2. Oxides of Lead, Poisoning by.—The most important oxide of lead in this relation is litharge or plumbic oxide (Muscicott), which is largely used in making glass and glazes for earthenware and iron. Those engaged in glass-making and grinding, glazing, pottery, &c., suffer. Owing to the solubility of lead-glazes, articles of food if acid may be contaminated. Litharge is also used for hair-dyes, japanning, &c., whence poisoning may result.

The 'red lead,' which is a mixture of lead oxides, has caused poisoning, by being used to colour wafers, adulterate snuff, and make putty or cement for tanks, &c.

3. Lead Salts, Poisoning by.—Of these the most important in this relation is the carbonate, or 'white lead.' Those engaged in the manufacture, grinding, and packing of white lead are the most frequent sufferers, and also those who largely use it, such as painters, glaziers, plumbers, glazed card manufacturers, lacquers, lace manufacturers, and those who apply it as a cosmetic (clowns, &c.) The acetate of lead has been used for correcting the acidity of wine and cider, and has been a frequent source of lead-poisoning. Poisoning has also occurred among seamstresses from using silk thread adulterated with it, in dye-works, where it is largely used, from using it as a hair-dye, and from long-continued medicinal administration. Lead colours, chromates, &c., have also caused poisoning, by being used to colour confectionery. From these and similar sources lead may be introduced into the system by inhalation, ingestion into the stomach, and apparently also by cutaneous absorption.

SYMPTOMS.—The affections caused by lead are frequently termed *saturnum*, owing to lead being the symbol of Saturn, the malign planet of the astrologers. They are of a manifold character and do not always occur in regular order or sequence.

Saturnum cachexia.—As a rule, after long-continued introduction of lead into the system, a saturnine cachexia is developed, characterised by anæmia, an earthy or dull hue of the skin, digestive derangement, dryness of the mouth, frequently a styptic or sweetish astringent taste, coated tongue, and fetid breath. The teeth are discoloured, and frequently appear elongated from retraction of the gums. At the margin of the teeth and the gums a bluish or violet line is developed. This, which is regarded as the specially diagnostic indication of lead-poisoning, was first described by Burton, and is shown to be due to the formation of a lead sulphide in the parts.

Lead Colic.—**SYNONYM:** *Colica Saturnina*; *Fr. Colique de Plomb*, *Ger. Bleikolik*.—Following the

symptoms just described, but sometimes without marked prodromata, a very characteristic affection occurs, namely, lead colic. This is known by many other synonyms, of which the more common are Painter's colic, Devonshire colic, Colica Pictorum, the last being derived from the inhabitants of Poictou, among whom in modern times it was first extensively prevalent, owing to adulteration of wine with lead-salts.

Patients affected with lead colic exhibit a encephalic look, earthy hue, blue line on the gums, coated tongue, and fetid breath; and suffer from nausea and, occasionally, vomiting. The bowels are obstinately confined, or scanty hard motions are passed with difficulty. Paroxysms of excruciating pain occur in the abdomen, which feels hard, and is retracted in the region of the umbilicus. The pain is of a truly colicky nature, and is relieved by pressure. The countenance is anxious, and the skin is covered with cold perspiration. The respiration is shallow, and the pulse generally slow and hard, though this is not always the case. The urine is not unfrequently almost or entirely suppressed.

Lead Palsy. **SYNONYM:** *Fr. Paralyse saturnine*, *Ger. Bleihlähmung*. After repeated attacks of lead colic, or it may be after one, and sometimes without antecedent colic, various other affections occur. One of the most common of these is a form of paralysis termed lead palsy, or, from its special features, 'dropped wrist.' The paralysis shows itself more particularly in the extensor muscles of the forearm, or region of distribution of the musculo-spiral nerve, and in consequence, when the arm is raised, the hand drops by its own weight. The paralysis generally commences in the extensor digitorum communis, and gradually extends to the other muscles supplied by the musculo-spiral, with the remarkable exception of the supinator longus. The paralysis does not necessarily confine itself to the forearm, for in advanced cases it may attack other muscles in the arm, the muscles of the leg, and the dorsal muscles, showing itself by preference in the extensor muscles of the body, and giving rise to a peculiar stooping, tottering gait. Aphonia occasionally results. The paralysed muscles undergo atrophy, and ultimately cease to react to faradisation or galvanisation, the faradic excitability being lost before the galvanic, as in peripheral paralysis generally.

Other phenomena.—Tendinous swellings of an oval or elongated shape frequently form on the tendons at the back of the wrist, and contrast prominently with the atrophied muscles. Neuralgic pains in the muscles and joints are often complained of. In the more advanced cases various forms of encephalopathies occur. Epileptiform convulsions are common; and psychical affections are not unfrequent, in the form of delirium, mania, or melancholia. Apparently in causal relation with lead-poisoning, disease of the kidneys and albuminuria may occur; and gout is frequently seen among those who work in lead. Abortion occurs to a large extent among women employed at white-lead works; according to Paul, in the proportion of sixty per cent. of those so employed.

The tendency is to recovery, if the cause of the symptoms is removed; but if not, the paralytic

and other affections become incurable, and death occurs in a miserable state of cachexia.

ANATOMICAL CHARACTERS.—There are no very characteristic appearances of chronic lead-poisoning. Lead is found in almost every organ and tissue in the body, the greatest quantity, according to Heubel, being found in the bones, next in the kidneys, liver, brain, and spinal cord, and to a less extent in the muscles.

Among the appearances which have been described are constriction and apparent thickening of the muscular coats of the large intestine, and an atrophic condition of the intestinal mucous membrane has been found by some authors (Kussmaul and Maier). These authors have also found an increase of the connective tissue, and atrophy of the nervous tissue in the abdominal ganglia of the sympathetic. The paralysed muscles exhibit atrophic degeneration, with hyperplasia of the connective tissue, and disappearance of the striæ, and the nerve-trunks likewise exhibit various stages of atrophy. We possess, as yet, no very reliable knowledge of the condition of the nerve-centres. The subject is one still requiring much investigation.

PATHOLOGY.—The mode of action of lead, and the causation of its characteristic symptoms are subjects still under discussion. Henle is of opinion that lead acts primarily on the non-voluntary muscular fibres throughout the body, while Heubel thinks that the primary action is on the nerve-centres. From this, as secondary consequences, are deduced the colic, due to irritation by compression of the intestinal nerves, and the constipation from cessation of the intestinal secretion by contraction of the blood-vessels. To the arterial ischæmia so produced the paralysis is attributed (Bärwinkel). Hitzig thinks that the paralysis of the extensors is due to a peculiar disposition of the veins, which favours the deposition of lead there. This is a mechanical theory which has little to support it except a dilated condition of the veins, and is utterly insufficient to account for the occurrence of paralysis in other regions, besides being in contradiction to the fact that lead is not specially deposited in the muscles, as this theory would necessitate. That the paralysis is due to degeneration of the nerves is in harmony with the symptoms and electrical reactions of the muscles, and is supported by the post-mortem appearances; but whether the peripheral degeneration is primary, or secondary to central degeneration in the anterior horns of the spinal cord, is not as yet satisfactorily determined.

TREATMENT.—In *acute* lead-poisoning from any cause the stomach must be emptied by the stomach-pump, or by emetics—of which sulphate of zinc is to be preferred. Solutions of the alkaline or earthy sulphates—of which the best is sulphate of magnesia—are indicated, with the view of forming the comparatively insoluble sulphate of lead, and expelling it from the intestines.

As regards *chronic* poisoning by lead, prophylaxis is the most important consideration. The great principles in lead-works are the inoculation of cleanliness; avoiding eating with unwashed hands, or in working clothes, or in workshops; moist grinding; free ventilation; precautions against dust rising, or wearing of flannel respirators where it is unavoidable; and occasional

doses of sulphate of magnesia, acidulated with sulphuric acid. Sulphuric acid lemonade has been recommended as a drink.

Workmen who begin to show signs of lead-poisoning should at once give up the work, and take to some other employment. As regards water-contamination, what has already been said on this subject will suffice to indicate the prophylactic measures.

In the treatment of *lead colic*, purgatives are indicated, and opium may be necessary to allay the excruciating pain. The sulphate of magnesia is the best purgative. Iodide of potassium is generally given with the object of removing the lead from the system, and is on the whole satisfactory in its results. A combination of the iodide with sulphate of magnesia is very beneficial. Sulphur baths are also recommended.

The local paralytic affections require local, in addition to the general treatment. Unless the muscles are in an advanced state of atrophy, and give no response to electrical stimulation, good results may be obtained by the use of the galvanic current applied to the muscles and to the musculo-spiral nerve. Faradisation has also been found beneficial, and is recommended by Duchenne, but the preference is to be given to the continuous current. D. FERRIER.

LEAMINGTON, in Warwickshire.—Sulphated common salt waters. See MINERAL WATERS.

LEECHING—The local abstraction of blood, by means of leeches. See BLOOD, Abstraction of.

LENS, Diseases of. See CATARACT.

LENTIGO—A synonym for freckle. See FRECKLES.

LEPIDOSIS (*Λεπίς* or *Λέπος*, a scale).—A term adopted by Mazon Good to distinguish the group of squamous affections of the skin; amongst which is included *lepra vulgaris* or *lepra*. The term is now obsolete.

LEPOTHRIX (*Λεπίς* or *Λέπος*, a scale, and *θρίξ*, a hair).—**DEFINITION.**—A term applied to a hair in which there is loosening and partial detachment of the overlapping edges of the scales of its cuticle.

Such hairs are usually met with in the axilla, and their peculiar conformation is attributable to the heat and dampness of that region, which causes maceration of the hair, particularly when it is of feeble structure. Sometimes the scales completely surround the hair; very commonly one side of the shaft is more affected than the rest, and presents the appearance of a fringe; and not unfrequently the scales are roughened with earthy and saline crusts deposited by the sweat.

TREATMENT.—The treatment most suitable for this evil is saponaceous ablation, followed by the use of a lotion composed of two to four drachms of oxide of zinc to half a pint of lime-water. E. RAMON WILSON.

LEPRA (*Λεπίς* or *Λέπος*, a scale).—The term *lepra* was used in the plural, *λεπρά*, by Hippocrates, to imply its constitution of multiple

atches. Willan adopted the term as significant of a squamous eruption, and in this sense it has been regarded as the *lepra Græcorum*. The foreign schools, however, prefer to name it *psoriasis*, a term now commonly associated with it in Great Britain, whilst they assign the word 'lepra' to 'the elephantiasis of the Greeks, the so-called 'true leprosy.' Hence whilst the operation of time has transferred the word 'psoriasis' to the lepra of the Greeks, it has conveyed the term 'elephantiasis' of the Greeks to the lepra of the Arabs; and common consent reserves the word lepra or leprosy for the elephantiasis of the Greeks. Thus, the terms, lepra, psoriasis, elephantiasis græcorum, and leprosy are somewhat confusedly intermingled, and one mode of extrication from the dilemma would appear to be to consider lepra as synonymous with leprosy, and to abandon its use in connexion with the lepra of the Greeks, now termed psoriasis, although the adoption of Mason Good's term 'lepræsis' would no doubt be the better alternative. For himself, however, the writer prefers the more classical course of retaining the term 'lepra,' the type of roughness, for the lepra Græcorum and the lepra vulgaris of Willan, giving to genuine leprosy, the great disease, its Greek designation, elephantiasis, and attaching psoriasis to squamous eczema, the 'psora' of the ancients, to which it properly belongs. The elephantiasis Arabum or 'elephant leg,' must be left out of consideration, as being an error of nomenclature, taking its origin in a blunder of translation of the Greek writings by the Arabian authors. See ELEPHANTIASIS ARABUM.

ERASMUS WILSON.

LEPROSY (*λεπρός*, rough) — DERIVATION AND SYNONYMS.—The term leprosy had its origin at a time when diseases of 'roughness' comprehended a large majority of affections of the skin, and it was, in fact, a generic name for 'skin diseases.' Hence the indistinctness of the word as we meet with it in the Bible, where 'leprosy' in one connexion represents a trivial disorder, and in another a serious disease, and in a similar sense, a leper, in many instances, was nothing more than a person afflicted with a cutaneous complaint. In modern times leprosy has been found a convenient designation for that terrible disease described by the Greek fathers of medicine as elephantiasis—a disease widely spread over the world, and, according to the saying of Aretæus, so much greater than the rest of diseases as the elephant is bigger than all other animals—a disease which is universal in its diffusion through the frame, and in which all the tissues of the body are implicated to a greater or less extent. The terms *leprosy* and *lepra* are consequently quite distinct from each other, leprosy and elephantiasis being synonymous; whereas the term lepra, or rather *λεπρά*, in the plural, was applied by the Greeks to scaly white spots of the skin, a disease of roughness as is elephantiasis, although a disease of roughness in a very different sense. But the analogy of the two words, both in derivation and sound, has given rise to some confusion, and the confusion is increased by a misapplication of the term elephantiasis. Thus we find that whilst the elephantiasis of the

Greeks has the signification of leprosy, the lepra of the Greeks is a trivial affection, sometimes styled lepra vulgaris, and very commonly, although erroneously, psoriasis. The word elephantiasis has also been applied to a local disease of hypertrophic growth known as elephantiasis Arabum, whilst the Arabians, amongst whom leprosy is also found, call that disease lepra. It therefore follows that leprosy, elephantiasis Græcorum, and lepra Arabum are synonymous terms.

The synonyms of leprosy are numerous, as may be inferred from the extensive distribution of the disease throughout the world, and its identification in different countries by different names. Amongst the most important of its synonyms are — *Elephantiasis, Lepra; Leprosælephantia; Black Leprosy, Red Leprosy, Elephantiasis tuberosa, asaræthra, nodosa, mutilans, leontina, satyria, Jani-evil, the Myrtle Ail or Great Disease*, its English name in ancient times, *la Lèpre* in France, *der Aussatz* in Germany; *Spedalskshed*, throughout Scandinavia; *Lakpra* in Norway, and so forth.

GEOGRAPHICAL DISTRIBUTION—The countries in which leprosy prevails most extensively are — Hindustan, China, the islands of the Indian Ocean, some of the Polynesian Islands, Madagascar, Africa, the West Indies, parts of South America, Norway, Sweden, and parts of Canada. Therefore, although most abundant in hot climates, it is likewise frequently met with in the North. For thirteen centuries it was endemic in Great Britain, the last case still lingered on the borders of Scotland so late as the beginning of the nineteenth century, now an indigenous example is nowhere to be found in the British Islands.

ÆTIOLOGY. The cause of leprosy is endemic. The disease has been met with from time immemorial in certain countries and localities; therefore the cause must be one which will be capable of abiding in different countries and in different climates—climates as various in character as the northern regions and the tropics. Time was when leprosy prevailed in Great Britain, and it took up its abode there for thirteen centuries; but the disease has gone, and therefore we may presume that the cause has ceased. Whether it has ceased in consequence of drainage and more general cultivation of the soil, is a question to be carefully considered. Hitherto indigenous leprosy has been unknown in the Australian colonies, but a well-marked case of elephantiasis tuberosa has recently come under the writer's attention, having its origin in New Zealand. The patient was a man of distinguished note in Australia, he had been draining very extensively in New Zealand, and he had lived for several years amidst the exhalations of the fresh-opened soil of the marshes. The example is not solitary. An English lad was born and brought up on the verge of a marsh in the West Indies. He was sent to London on account of debility; the diagnosis was elephantiasis. A few years afterwards, his father, an officer of police, followed him home, a victim of the same disease, which had become developed since the departure of his son. The writer could multiply cases of this kind considerably, and has had the conviction

susceptibly borne in upon him, that the cause of leprosy is miasma. No other cause is of such general distribution, suiting every climate and every part of the world, unless it be such countries as have been relieved of the cause by land-culture and improvement. Leprosy has been assumed to be caused by bad food, and by a fish diet. There can be no doubt that an improper diet may be quite equal to the production of debility and disease, and might predispose, like any other lowering course, to the invasion of a miasma; but the disease prevails amongst the well-nourished as well as amongst the ill-nourished, and in countries where fish is rarely or never eaten; whilst fish in moderation must be regarded as a most healthful and nutritious article of diet. Leprosy is now believed to be hereditary, and it has the character of being non-contagious. Nevertheless there are some curious histories on record of the first appearance of leprosy in a population after the immigration of foreigners from a leprosy country, as in the example of the importation of negroes into the district of Surinam in South America, and the origin and spread of the disease among the Sandwich Islanders after an immigration of the Chinese. This and other questions of cause must still remain unsettled until further information is obtainable. A specific form of bacillus has recently been found in leprosy, the lymphatics being believed to be the channels of infection. See *Lancet*, July 30, 1881.

ANATOMICAL CHARACTERS.—The morbid anatomy of leprosy centres chiefly in the integument and in the nervous system. Danielssen and Boeck found the sheaths of the cutaneous nerves thickened and distended with exudative deposits, and similar changes were seen in the spinal cord. They also discovered tubercular matter in several of the internal organs, glands, and viscera. Virchow is of opinion that the pathological element of elephantiasis differs in no essential respect from that of the gummata of syphilis, nor indeed from that of lupus and glanders. Granulation-tissue is the characteristic element of all the three; the granulation tumour of elephantiasis is, however, more permanent than others of the same class, and tends in a less degree to degeneration and softening. Dr. Moxon, in a well-marked case of elephantiasis tuberosa that fell under his examination in Guy's Hospital, regarded the pathology of the disease as especially evinced by the integument, which he found atrophic and disorganised, the nerves apparently healthy, but the cutaneous nerves and veins alike involved in dyscrasic degeneration. 'We are struck,' he observes, 'with the small amount of morbid change proper to elephantiasis. The immediate cause of death was amyloid or lardaceous disease of the alimentary canal, liver, kidneys, and spleen, with marasmus in the most extreme degree, occurring as in other lingering but not otherwise mortal maladice.' See *BACILLI*, in APPENDIX.

SYMPTOMS.—Leprosy makes its beginning so lightly and so unobtrusively, that it is perhaps rarely detected in its earliest stage. At that period there might, after close examination, be discovered a few symptoms of debility, such as lassitude, chilliness, failure of appetite, sleepi-

ness, and lassitude. But these symptoms subside after a while, and the patient recovers his wonted energy and power, some months later similar symptoms return, but somewhat intensified, and several such recurrences may be experienced before any more obvious symptoms are made evident. The symptoms resemble those produced by malarious poison, and may be regarded as indicating the incubation of the leprosy virus.

These premonitory symptoms of leprosy acquire force after repeated recurrence; and then two other symptoms make their appearance, namely, a hyperæmia of the skin, and a defective sensibility of the peripheral branches of the spinal nerves. The hyperæmia of the skin generally assumes the form of circular spots, sometimes of uniform size, at other times of blotches of irregular shape and varied extent. The isolated spots appear commonly on the trunk of the body and fleshy parts of the limbs, whilst on the face and neck, and on the hands and feet there is an uniformly diffused redness. What has already been said with regard to the progressive development of the constitutional symptoms must be repeated with respect to the local signs of the disease. At first only the face, hands, and feet may be congested, with a few spots on the trunk of the body. Then the hyperæmic congestion will subside and remain quiescent until another exacerbation of the leprosy fever is imminent, when the spots will be increased in number and deepened in colour.

The redness of leprosy is dull coppery or purplish in tint, as it subsides it leaves on the skin a pigmentary stain, the affected integument is puffy with serous infiltration, the pores are dilated as if from hypertrophy of the follicles, and in general appearance the skin resembles the rind of an orange. At a more advanced stage of the cutaneous disorder the hyperæmic congestion becomes centrifugal, and the circular spot is developed into a ring, even the pigment disappears from the centre of the blotch, leaving a bleached centre surrounded by a belt which is slightly tumid, of a dull red hue, and deeply pigmented. Eventually the whole of the affected part may be represented by a white blotch. Blotches of all the three kinds may be seen at the same time dispersed over the body, some being red only, some melanæmic, some leucæmic, according to their age; and others of irregular figure, arising from the blending of the circular spots, or spread out into rings of various extent.

The distribution of the maculæ or blotches of leprosy on the surface of the body corresponds with the nerve-territories of the integument, and the same may be said with regard to the face, and the extremities below the elbows and knees. On the face the parts specially affected are the superciliary regions, the nose, and the ears, and on the arms the territory of the ulnar nerve. In all these regions the blotches soon become blended; and the redness, pigmentation, and infiltration are more general than elsewhere. The suffused redness of the skin has suggested the term elephantiasis erythematosa; and this state of congestion is frequently accompanied by prominence of the follicles, and more or less desquamation and exfoliation of cuticle. In some

situations the hyperæmic blotches are moistened by a greasy exudation; in others they are dry, parched, and rough.

In all the affected parts of the skin there exists a certain degree of numbness or anæsthesia. In the early stages of the disease there is scarcely any pain; nevertheless, if the ulnar nerve be pressed against the inner condyle, the pain is frequently acute, and the same occurs from pressure on the peroneal nerve. As a consequence of imperfect innervation, the fingers are frequently slender and numbened; they are brown from pigmentation; and the metacarpal spaces between the forefinger and thumb is hollowed, from defective nutrition of the abductor muscle.

VARIETIES.—Starting with one uniform series of premonitory symptoms, leprosy after a while evinces a remarkable tendency to pursue an elective course. In the great majority of cases the prime seat of manifestation of the disease is the integument and mucous membrane; this constitutes the form of the disease known as *elephantiasis tuberosa*. In a smaller number of cases the affection of the nervous system, and particularly loss of sensation, are most conspicuous; and this constitutes the group called *elephantiasis anæsthetica*; whilst a sub-group of *elephantiasis anæsthetica* is remarkable for dislocation and amputation of the members at the joints, constituting *elephantiasis nodosa*, joint-evil, or *elephantiasis mutilans*.

In the tegumentary or tuberosus group, the conspicuous symptom is the development and gradual growth of solid papules or tubercles in the skin. These originate in the centre of the hyperæmic spots already mentioned, and do not make their appearance until after the disease has existed for several months. At first they are reddish in colour; afterwards they differ little in tint from the surrounding skin. They range in size from two lines to half an inch in diameter, and are slightly convex at the summit, and hard to the touch. Their development follows the progressive exacerbations of the leprosy fever; they grow while the febrile process continues, and become stationary when it abates; each exacerbation, however, adds to their bulk, and forces them on to maturity. Having reached the mature stage, they soften and break up; an ulcer is formed, which discharges for a while; and then the ulcer heals. A common seat of the tubercles is the region of the eyebrows, which they denude of hair, they also give a frowning aspect to the countenance, and when of large size add a leonine fierceness to the expression, which has suggested the term *elephantiasis leonina*. Similar phenomena to those already described manifest themselves in the fauces, the nasal cavities, and the larynx—at first hyperæmic macule, then tuberosus prominences, and next ulceration, so that the symptoms in this region are usually severe. The voice is hoarse; the nasal passages are plugged; occasionally the septum ulcerates; and sometimes the nasal bones fall in. Tubercles likewise form along the edges of the eyelids; the conjunctiva is inflamed and thickened; the cornea becomes opaque; and sometimes the eyeball is destroyed. The lips are rendered protuberant by the tubercles, and

ulcerate like the rest. The external ear is likewise enlarged and studded with tubercles, and the lobule of the pinna is remarkably elongated, suggesting, with the large tubercles on the forehead, the features of the typical satyr. Finally, the leprosy congestion extends to the scalp; the hair falls off, as it does on the eyebrows; and the term *elephantiasis alopecia* receives some corroboration. On the trunk of the body the ulcers are frequently of considerable extent; and occasionally the limbs have the appearance of being stripped of integument from the shoulders to the hands.

The ulceration of elephantiasis is not, however, restricted to the softening of tubercles; instead of, as in this instance, beginning from without, it starts in its most extensive forms from within. There is at first a general swelling of a part, such as the heel or the joint of a great-toe; a blister is raised on the skin covering the swelling; the cuticle is rubbed off; and an ulcer is quickly established. All this may occur without pain and almost without the knowledge of the patient. A large quantity of a glairy, colourless fluid is poured out by the ulcer; the sore is æsthenic and sluggish; in the case of a joint the bone may be exposed, and very probably the end of a phalanx will be forced through the opening, to be followed in due time by the rest of the bone; then the ulcer contracts; the cavity closes up; and the integument heals. After a time a similar process commences in the great-toe of the opposite foot, or in the joint of a thumb, and runs the same course—either the extrusion of a bone or the healing up of an æsthenic sore, after a continuance of several weeks or months. The joints of the phalanges of the feet and hands are similarly attacked from time to time, and a considerable amount of deformity of these members results. But it is worthy of note that while these morbid processes are all of them subject to the periodical canon of the disease, they alternate in their occurrence; and it is to be further noted that an excessive discharge from one of these ulcers has a derivative influence, and communicates a sense of relief to the whole system.

Elephantiasis anæsthetica differs from *elephantiasis tuberosa* in the more decided manifestation of disorder of the nervous system. There are the same premonitory symptoms, the same hyperæmic spots and blotches on the skin, the same pigmentary macule; but there is an absence of tubercles and ulceration, the numbness and anæsthesia are more decided, a general state of atrophy creeps through the system, and the sufferer is prostrated by exhaustion. Neuralgic pains, which are not wholly absent in *elephantiasis tuberosa*, are more obtrusive in *elephantiasis anæsthetica*. A sense of dulness and heat pervades the surface; and there are sensations of tingling and pricking, and of burning heat. Whilst the integument is insensible, there are deep-seated burning pains, sometimes of a bone or joint, and sometimes of the vertebral column. These pains are greatest at night; they prevent sleep, and give rise to restlessness and frightful dreams. Moreover, the skin, robbed of its sensation, is prone to vesication and excoriation, and the latter frequently ends in ulceration. The

anesthesia is often so great that the contact of fire or of the severest caustics occasions no sensation.

Elephantiasis mutilans is more local in its characters than either of the preceding; it is wanting in the tegumentary manifestations of elephantiasis tuberosum, and although essentially anæsthetic in its nature, the anæsthesia is local, and affects chiefly the limbs. In this form of the disease loss of the bones of the hands and feet is a conspicuous symptom; and not unfrequently the limb is lopped off painlessly at the ankle or knee, or at the wrist or elbow. When the phalanges and metacarpal or metatarsal bones are alone attacked, the last phalanx, probably from its higher vascular organisation, is generally spared; this may be the case even when the bones of the wrist are eliminated; and the hand or foot in this case is crumpled up, resembling a confused bunch of tips of fingers or toes. Often the bones are ejected; in these cases the integument heals in the most complete manner, and it is in similar cases, where considerable reparative power is obviously present, that spontaneous cure is most likely to occur. In elephantiasis anæsthetica the nervous system is too deeply and seriously implicated to admit of spontaneous cure; and in elephantiasis tuberosum the tegumentary system, both cutaneous and mucous, is likewise too extensively damaged to render cure a rational expectancy.

PROGNOSIS.—The prognosis of leprosy is essentially unfavourable. A disease which tends to the continuous degeneration of the skin and mucous membrane, with general dyscræmia of the entire organism, which is impelled onwards by a law of periodic progression, and which has no tendency to spontaneous resolution, must necessarily be fatal, the only question being one of duration. A very few instances are on record in which individuals afflicted with this disease have survived, and these principally from amongst the cases of elephantiasis mutilans; but such instances must be regarded as the rare exception, rather than the rule. The tuberosum form of the disease is more rapid in its termination than the anæsthetic form, and the duration of life in both ranges from about ten to twenty years.

TREATMENT.—The treatment of leprosy resolves itself into, first, the employment of means intended to promote improvement in the general health; and, secondly, the adoption of such empirical remedies as have acquired a favourable reputation for the cure of the disease. In the first category we must place the removal of the patient from the locality wherein the disease has been engendered, and possibly to one where the disease is unknown. Next would follow a liberal and generous diet, such as animal food and beer; with active exercise. Thirdly, tonic and nutritive remedies, such as cod-liver oil, iron, quinine, strychnine, bitters, and phosphates, should be given. Nitric acid has been praised by one physician, and acetic acid in combination with carbolic acid by another. There can be no doubt that under a generous regimen the patient will improve in health and strength; the constitutional manifestations of fever will be less frequent, and hope will gleam in the mind, both of the physician and the patient; but cure, either in or distant as ever.

Specific alteratives have been exhausted with equal want of success. Iodine has failed. Danielsen and Boeck administered arsenic largely; and the perchloride of mercury has been extensively used by Benquerthuy. When these and other remedies are employed judiciously, in combination with a generous diet, moderate exercise, and thorough stimulation and inunction of the skin, the symptoms invariably improve for a time; but the disease as certainly falls back into chronic sluggishness and smouldering inactivity when they are relinquished or neglected.

The principal empirical remedies which have been recommended in this disease are:—the *acalepias giganteæ*; hydrocotyle asiatica; veronica quinquefolia; chaulmoogra oil, and gurgun balsam. The *acalepias* or *rumex giganteus*, the mudar of Hindostan, has received the name of vegetable mercury. The part of the plant employed medicinally is the root-bark, reduced to powder; and the dose of the latter is half a drachm daily. The hydrocotyle asiatica, in the form of powder of the dried plant, is given in doses ranging between one and six grains daily, and is also administered as an infusion, a syrup, and an extract; its active principle is vellarine. The medicinal part of the veronica quinquefolia is its root, and ten ounces of the root has been mentioned as a quantity sufficient to cure a leprosy. The chaulmoogra oil is procured from the seed of an Indian tree, the chaulmoogra or gynoecardin odorata. It is administered both internally and externally, the dose for the former purpose being six to twelve minims, three times a day. A tincture of the plumbago rosea has also been found serviceable in cases of anæsthetic leprosy; the dose being one drachm three times a day.

More recently Dr Joseph Douglass has recommended gurgun balsam or wood oil as a very promising and successful remedy. It is an oleo-resin, obtained from one of the species of the *dipterocarpus* tree of India; and is given in the form of an emulsion, in combination with an equal proportion of lime-water, the dose of the emulsion ranging between two and four drachms twice a day. Or it may very conveniently be administered in capsules, each containing a drachm.

The local treatment of leprosy consists in stimulation of the skin by means of hot-air baths, followed by frictions and inunction with bland and stimulating oils. Ointments and liniments of the specific remedies already mentioned, namely, mudar, hydrocotyle, and gurgun, have been used for this purpose, as well as for drawing the ulcers. Danielsen and Boeck employed counter-irritants in the course of nerves presumed to be affected, with cupping and moxæ to the spine in anæsthetic leprosy; whilst they treated the tubercles of tubercular leprosy with the acid nitrate of mercury, and with a strong solution of potassa fusa. Benquerthuy found benefit result from the acid irritating oil of the shell of the cashew nut (*Anacardium orientale*) used as a blister to the tuberculous skin; a copious exudation followed the application, and relieved both the local and the constitutional symptoms. The gurgun treatment is accompanied by energetic frictions with a liniment composed of equal parts of the balsam and lime-water, the same as the emulsion

taken internally; and asthenic ulcers are pencilled with a solution of chloride of zinc.

A review of these various methods of treatment, and a consideration of the personal attention required by the patient suffering under this terrible disease, are suggestive of the observation that it can only be effectually treated in an institution devoted especially to the purpose.

ERASMUS WILSON.

LEPTOMENINGITIS (Λεπτός, delicate or thin, and *meningitis*).—A term signifying inflammation of the pia mater. By its use, in association with arachnitis and pachymeningitis, we are enabled accurately to indicate the precise seat of inflammation involving the meninges of the brain or spinal cord. There is a practical convenience, warranted by pathological facts, in retaining the term arachnitis, although anatomists are not now disposed, as they were formerly, to believe in the existence of an arachnoid membrane, distinct, externally from the dura mater, and internally from the pia mater. See MENINGES, Diseases of.

LEPTOTHRIX (Λεπτός, delicate or slender, and *thrīx*, a filament or hair).—*Leptothrix buccalis* is a name assigned by Robin to certain vegetable parasites or minute filaments, which can be recognised by means of the microscope, amongst the epithelial scales of the tongue or other parts of the mouth; and especially between the teeth, or in the hollows of decayed teeth. They occur in healthy persons, as well as in the sick, and have in this situation really no pathological signification. Organisms of the same kind are, however, now commonly named *bacilli*, and have during the last two or three years been recognised as exceedingly common in many organic solutions, and also within the blood and tissues of animals and of man suffering from splenic fever (see PUSTULE, MALIGNANT). Some regard them as constituting a distinct genus, whilst others believe them to be only one of the multitudinous forms that may be assumed by bacteria, when growing in certain kinds of media. See BACTERIA, and MICROCOCCI.

Dermatologists also employ the term leptothrix to indicate a morbid thinness and weakness of the hair.

LESION (*ledo*, I hurt).—This word originally signified a hurt or injury, but its use is now extended to comprehend all organic changes of a morbid character, affecting an organ or tissue.

LETHARGY (Λήθη, oblivion, and *ἀργία*, idleness).—A disorder of consciousness, which consists of prolonged and profound sleep, from which the patient may be momentarily aroused, but into which he falls off again immediately. See CONSCIOUSNESS, Disorders of; and TRANCE.

LEUCIN (Λευκός, white).—This term has been applied to blotches in the skin of a white colour; and hence it has alternately been confounded with lepra alpeoides, with vitiligo, and with the leucodermic blotches of leprosy. It seems, however, more than probable that the pathological condition intended to be signified by this word, is a circumscribed sclerodermia, namely, that which we at present term *morphea alba*. See MORPHEA.

ERASMUS WILSON.

LEUCIN (Λευκός, white).—Leucin, the chemical composition of which is $C^6H^{10}NO_4$, is a product of decomposition of albuminous bodies. It may be obtained from them by the action of caustic alkalies, or by long boiling with sulphuric acid. It is found in the secretion and substance of the pancreas, in the spleen, thymus, thyroid, suprarenal bodies, lymphatic glands, salivary glands, liver, kidneys, and brain. It is also found in old scales of the epidermis, and in ichthyosis, old toe-nails, and sebaceous cysts. Pathologically it occurs in abundance in the urine and liver of those who die of acute yellow atrophy; and, it is said, in the urine of those suffering from severe typhoid and variola, although there is no chemical proof of this. Leucin is thought by some physiologists to be a stage in the decomposition of albuminous matters into urea. Under the microscope it is seen as round balls, having some resemblance to drops of oil, sometimes hyaline, sometimes with radiating marks, sometimes with concentric rings. The test for leucin with the microscope is very untrustworthy taken alone. Nearly every urine can be made to give this evidence. If leucin is to be looked for, it must be separated by the following process. The urine is precipitated with acetate of lead, filtered, and the excess of lead removed from the filtrate with sulphuretted hydrogen. The filtrate must be next evaporated to dryness; the residue extracted with boiling alcohol and filtered; and the filtrate evaporated to a syrup. If leucin be present, it separates in the form of the crystals described above. Chemical tests must now be applied to the crystals. A small portion is evaporated to dryness in a platinum crucible with nitric acid; and if leucin be present, a colourless, almost invisible, residue is left, which becomes yellow or brown when warmed with a few drops of soda solution. Leucin is almost always found associated with tyrosin. See TYROSIN.

J. WICKHAM LING.

LEUCOCYTHÆMIA (Λευκός, white, κύτος, a cell, and *αἷμα*, blood).—*STROM.*: *Leukæmia* (Virchow); *Splenopneuthia leucocythæmia* (Huxl.); *Fr. Leucocythémie*; *Diathesis lymphatica à forme leucémique* (Jaccoud); *Ger. Leucocythæmia*.

DEFINITION.—A chronic disease, in which there is a considerable and permanent increase in the number of the pale blood-corpuscles; usually associated with enlargement of the spleen, sometimes also with that of the lymphatic glands, and with disease of the medulla of bone.

The term leucocythæmia proposed by the late Dr. Hughes Bennett is a convenient and significant designation, the essential feature of the disease being the excessive proportion of leucocytes in the blood. The term *leukæmia*, proposed by Virchow, is less obviously accurate, since the blood (as Purkinje urged) although appreciably paler than normal, is not white.

Excess of leucocytes in the blood, slight or transient, is known as leucocytosis, and is met with in many morbid states. Permanent excess, sometimes considerable, but rarely very great, also occurs, associated with a primary enlargement of the lymphatic glands.—*Lymphatic leucocythæmia.* These cases differ in many important respects from the cases of leucocythæmia.

elated with primary enlargement of the spleen; so that it is most convenient to describe them in connection with lymphadenoma, and to consider here only cases of splenic leucocythæmia. See *LYMPHADENOMA*.

HISTORY.—Fallor of the blood, as if pus were mixed with it, was noted by Bichat in the beginning of this century; and the combination of this appearance with enlargement of the spleen, was observed by Velpeau in 1827. The dependence of this alteration in the blood on an excess of pale corpuscles was described by Donné in 1844, and interpreted by him as due to imperfect transformation of white into red corpuscles. In 1846, two cases of the disease were published together, the one by Dr Craigie, the other by Dr. Hughes Bennett, and to the latter appears to belong the credit of recognising the salient features of the affection as a distinct malady. A month later, however, Virchow published another case, independently and admirably worked out. In all these cases the change in the blood was only recognised after death. It was first observed during life in 1846, by Dr. H. W. Fuller, and subsequently by Dr. Walsh. In Germany the first case was diagnosed during life, by Vogel, in 1848. Since then numerous cases and descriptions of the disease have been published, of which the more important are those of Virchow, Hughes Bennett, Vidal, Huss, Ehrlich, and Mosler.

ÆTIOLOGY.—In only a small proportion of cases of leucocythæmia can any causation be traced. Race, as such, seems to be without influence. Heredity has only been traced, as a history of splenic disease in ancestors or collaterals, in one or two isolated instances. The disease is twice as frequent in men as in women. It may occur at all ages. It is very rare under the age of ten, and the numbers gradually rise, taking both sexes, to the decade between thirty and forty, when nearly one-third of the total occur (46 out of 154 cases). After forty they fall in each decennial period. In females, however, the maximum is reached in the period between forty and fifty, and of eleven cases over sixty collected by the writer, only one was in a woman. Position in life appears to exercise no influence on the occurrence of the disease. Depressing influences, inanition, over-exertion, and especially depressing mental emotion, are antecedents which have been occasionally noted. Sexual processes, in women, appear to have a distinct influence. The disease has been seen to be most frequent, in them, during the climacteric decade, and practically to cease when the menstrual epoch is over. In some cases the disease has commenced during pregnancy; in a larger number it has succeeded parturition. Injury to the spleen seemed, in one or two recorded cases, to be the cause of the disease. Small-pox, typhoid fever, acute rheumatism, pneumonia, and syphilis, have been supposed to be causes of the affection, but the ætiological relation is doubtful. Of all antecedent conditions, intermittent fever is incomparably the most frequent. In one-fourth of the total number of cases (159) analysed by the writer, there was a history either of ague or of residence in an ague district. The interval between the malarial affections and the disease varied from a

few months to thirty years. The fact that, in many cases, a long period elapsed, and that the attacks of ague, in some instances, were trifling, makes it probable that, in the cases in which the patients had merely lived in an ague district, the malarial influence, which did not cause ague, led to morbid changes which eventuated in the leucocythæmia. One patient under the writer's care, a middle-aged woman, had lived in a malarial district only during the first few years of her life, but, shortly before her birth, her mother had suffered from an attack of ague.

ANATOMICAL CHARACTERS.—*Blood.*—The blood, as seen after death or during life, is paler than normal, and may even be greyish-red in colour. In extreme cases coagulation is imperfect; a grumous chocolate-brown mass results. After debarrassment three layers form—red corpuscles, pale corpuscles, and liquor sanguinis. Under the microscope the pale corpuscles are seen to be in great excess: instead of two or three per field, as in the normal, there may be several hundreds. Enumeration (see *HEMAGNOMETRY*) shows that not only are the white corpuscles increased, but the red are lessened out of proportion to the increase in the white, so that the total number of corpuscles is always diminished. Instead of the normal 5,000,000 per cubic millimetre, there may be only 2,500,000 or even 1,150,000 (50 and 23 per cent. of the normal). The proportion between the white and red varies, being 1-20, 1-10, 1-5, 1-2, or 1-1; or the white may be the more numerous. The apparent is greater than the real excess of white, in consequence of the closer contact of the red. It was proposed by Magnus Huss to regard as leucocythæmia only those cases in which the proportion is greater than 1 to 20, and the rule has been largely followed, but it must be remembered that in commencing cases the proportion may be smaller than this. The greatest change hitherto recorded was a reduction of the red from 5,000,000 to 470,000 per cubic millimetre (9 per cent. of the normal), and an increase of the white to 680,000 per cubic millimetre instead of 15,000, the normal average. The pale corpuscles may be of normal size; but usually some are large; and often many are smaller than normal (the *globulins* of Donné), especially when the lymphatic glands are affected. Reagents bring into view one to four nuclei. Some of the corpuscles present obvious fatty degeneration. The red corpuscles are usually normal in appearance, sometimes unduly pale. Nucleated coloured corpuscles have been seen in a few cases, believed to be intermediate forms between the white and red corpuscles. The specific gravity of the blood is lessened from 1.055, the mean in health, to an average of 1.042; the change being due to an increased proportion of water, from 790 parts per 1,000 in health, to 840 in leucocythæmia. The fat and fibrin are increased, and the latter sometimes presents a peculiar granular appearance. The iron is lessened. Abnormal constituents have also been found in the blood, such as the albumin of Reichardt, mucin, a substance analogous to gluten, hypoxanthin, lactic and formic acids. Minute octahedral crystals have been found in the blood and in many organs after death, about $\cdot 016$ mm. in

length. Their nature is uncertain. Since they have been found only after death, it is conjectured that the substance of which they consist is held dissolved during life. They are not peculiar to this disease.

Organs.—The *spleen* is always enlarged, sometimes extremely. Its weight varies from twice to fifty times the normal—1 lb. to 18 lbs. The average of 72 cases analysed was about 6 lbs. The average length is nearly 12 inches. The enlargement is commonly uniform; the shape of the organ being preserved. The surface is smooth, but often presents traces of local peritonitis, in the form of yellowish opaque patches. It is frequently adherent to the diaphragm, omentum, abdominal wall, intestines, or liver. Its consistence is usually increased, rarely diminished. The cut surface is smooth, and yields comparatively little blood; it is brownish-red, or even brownish-yellow, mottled with paler lines, due to thickened trabeculae. The Malpighian follicles are not usually conspicuous. In cases which begin with enlargement of the lymphatic glands, and which are really cases of primary lymphadenoma, the Malpighian follicles may be so enlarged as to constitute small growths. There is rarely an area of distinct softening. Wedge-shaped, yellowish-white, caseous portions are frequent, and are evidently infarcts, when recent they are deep red. The histological change in the organ is an overgrowth of the splenic pulp, the trabecular tissue is increased; and so also is the retiform tissue of nucleated fibres and cells, among which the lymphoid corpuscles lie. The Malpighian bodies may not be discoverable with the microscope, or they may be found to have undergone fatty or lardaceous degeneration. The infarct-like masses present the splenic tissue-elements in a state of fatty degeneration. In many cases the crystals, already described, have been found in the spleen in great abundance. This organ has been found by analysis to contain gluten, glycocoll, hypoxanthin, xanthin, leucin, and tyrosin.

The *lymphatic glands*, some or many, are enlarged in one-third of the cases of primarily splenic leucocythæmia (51 out of 167 cases). The order in which the several groups are affected is, beginning with the most frequent, the mesenteric, cervical, inguinal, axillary, retro-peritoneal, thoracic, portal, and iliac. In only five cases was the change universal. The enlargement is not considerable, the individual glands rarely attaining the size of a walnut. They are usually smooth, soft, grey, or reddish-white on section; rarely caseating or suppurating; sometimes presenting hemorrhagic extravasations. Their minute structure differs little from the normal. Lymphoid corpuscles lie in an adenoid reticulum, which is rarely increased, as it is in lymphadenoma.

With respect to the *alimentary canal*, the gums are occasionally swollen and ulcerated, the swelling being due to infiltration of the gum with leucocytes, or to an actual lymphoid growth. The tonsils and follicles of the tongue are sometimes enlarged by lymphoid growth; and there may be a similar change, usually slight, in the lymphoid tissue of the wall of the stomach, and much more considerable in the

solitary and agminated glands of the small intestine. These growths frequently ulcerate. Similar changes are also found in the large intestine. The *peritoneum* sometimes presents similar growths. The *liver* is enlarged in at least two-thirds of the cases, varying in weight from 5 lbs. to 14 lbs. In some cases of slight enlargement no structural change beyond congestion has been found, frequently, however, there are disseminated lymphoid growths, minute, greyish-white, commonly interlobular in position, often surrounding branches of the portal vein. The capillaries are always distended with pale corpuscles. Fatty degeneration of the liver-cells is also common. The *kidneys* are abnormal in at least one-half of the cases. They may be simply pale from anemia; pale and enlarged, from granular degeneration of the cells, and distension of the capillaries with leucocytes; or they may present minute growths similar to those in the liver, and situated between the tubuli of the cortex, especially near the glomeruli. Marked fatty degeneration of the kidney has also been found. The *suprarenal bodies* have been found diseased in several cases, and in one or two there was bruising of the skin. The *thymus* and *thyroid glands* have also been found enlarged. The *heart*, as in other cases of intense anemia, may present granular and fatty degeneration. Extravasations of blood have been found beneath the endo- and pericardium. Its capillaries are often distended with leucocytes. Pericardial effusion is common. The *lungs* may present simply distension of capillaries, or hemorrhagic infarcts, or actual growths, similar in structure to those found elsewhere. These commence at the bronchi and infiltrate adjacent tissues. Rarely they may break down and form cavities. Pleural effusion is very common, and lymphoid growths have been found on the membranes. In the *brain*, hemorrhages, usually multiple, constitute the most frequent change. Minute growths in the membranes, distension of the meningeal vessels with pale blood, and their obstruction by masses of leucocytes (Bastian), have also been recorded. The *skin* is, in rare cases, the seat of growths. The *bones* have lately been found diseased in many cases (Ranvier, Neumann, &c.). The marrow is grey or reddish-grey, diffuent, and presents lymphoid cells and blood corpuscles. Sometimes cells intermediate between white and red corpuscles have been found in it. The vessels are fewer than normal. The change may be found in all the bones, most marked in those which possess most spongy tissue, as the ribs and vertebrae, but also considerable in the long bones. Externally the bones may be normal or enlarged. The compact substance may be reduced in thickness, and even perforated (Mosler). The *retina* is frequently diseased. Hemorrhages may be found, especially in the nerve-fibre layers, and adjacent to them the retinal elements may be degenerated. The capillary vessels are filled with pale corpuscles, and actual lymphoid growths have also been found.

Symptoms.—Of the early symptoms of leucocythæmia, the most frequent are those due to the splenic enlargement, namely, abdominal fulness, pain, or an actual tumour. Next in frequency is

weakness. Hemorrhage, especially epistaxis, often occurs early, but rarely before other indications of ill-health. The change in the blood causes pallor of skin and mucous membranes, shortness of breath, and all the indications of anemia. To its defect a large number of the symptoms to be described are due. The altered characters of the blood, readily observable during life, have been already described. The temperature is frequently, but not invariably, raised. It is commonly higher in the evening than in the morning; the evening rise usually reaching 101° – 104° . The morning fall may be considerable or slight. Sometimes periods of considerable pyrexia alternate with others in which there is little fever. The cases in which there is most pyrexia are usually, but not always, those of most rapid course. The enlargement of the spleen presents the typical characters of a splenic tumour. It may occupy the whole left half of the abdomen, extend even beyond the middle line, descend into the iliac fossa, and even into the pelvis, so as to be perceptible by vaginal examination (Spencer Wells). It may vary in size from time to time. Friction may sometimes, and a *bruit de soufflet* rarely, be heard over it. It usually causes an unpleasant sense of distension, is often tender, and sometimes is the seat of spontaneous pain. By its pressure it may raise the heart, cause considerable dyspnoea, and interfere greatly with the functions of the stomach. The distension of the abdominal wall may cause lines, similar to those of pregnancy, to appear over the spleen, and their position is sometimes distinctly determined by the course of vessels. The enlargement of the glands is rarely sufficient to give rise to other symptoms than the obstructive evidence of their presence. The glands thus present, in this disease, a marked contrast to their condition in lymphadenoma. They often lessen in size before death. The alteration in the bones is usually unattended by symptoms. Rarely they become distinctly enlarged and tender. The action of the heart is disturbed by both the anemia and the displacement. The pulse is frequent; and palpitation is common. The circulation is impeded; effusion of serum into the cellular tissue of the body is almost invariable in the later stages of the disease. Slight ascites is frequent, and great effusion is sometimes due to the pressure of enlarged glands on the portal vein. Hydrothorax is also common. The most striking circulatory symptom is hemorrhage, which occurs in a large proportion of cases, most frequently from the nose, and less frequently from the bowels, stomach, lungs, uterus, into the skin, brain, joints, cellular tissue, or peritoneum. The hemorrhagic tendency is so great that slight injuries may give rise to serious loss of blood; the extraction of a tooth, or the puncture for paracentesis, has thus led to death; while most cases in which excision of the spleen has been attempted have been fatal from the same cause. The respiration is usually interfered with, partly from the splenic enlargement, and partly from the anemia; that due to the former is increased by the recumbent posture. The anemic dyspnoea may be unnoted when the patient is at rest, although any considerable movement causes an agony of breathlessness. The dyspnoea is also increased by changes in the lung, bronchial catarrh,

and the frequent pleural effusion in the later stages. Cough is frequent, and may be an early symptom of the disease. The change in the gums, already described, may lead to ulceration—the ‘leukemic stomatitis’ of Mosler; but it is more rare in this disease than in lymphadenoma. The gastric functions are chiefly interfered with by the pressure of the spleen, which causes dyspepsia, and often vomiting. Diarrhœa is extremely common, and may be accompanied by hemorrhage. The enlargement of the liver may be recognised during life, but rarely gives rise to subjective symptoms. Jaundice only results from compression of the bile-ducts by enlarged glands. A yellowish tint of skin is, it may be remarked, frequent, apart from true jaundice—the ‘icterus leucalis’, it probably results from the anemia, the altered blood being unable to destroy the bile-pigment absorbed into it from the intestine. The urine varies in amount, but is usually strongly acid, and of high specific gravity. The amount of urea is unaltered, that of uric acid is increased. Hypoxanthin, lactic acid, and formic acid have been found in it. Albumin is rare, apart from structural changes in the kidneys. Menstruation is usually arrested. The functions of the nervous system are disturbed by the altered blood, languor, timidity, and vertigo are frequent; and slight mental failure, delirium, and coma are occasionally met with. The graver symptoms are probably due to capillary obstruction by masses of leucocytes, or to small hemorrhages. Besides the noise in the ears, deafness is common, especially towards the end. In the fundus oculi, changes may usually be seen with the ophthalmoscope. The pallor of the blood in the retinal and choroidal vessels is conspicuous. The retinal veins become very broad, and are often tortuous. Extravasations of blood are almost invariable at some period, usually striated, sometimes rounded. Yellowish or white spots are sometimes seen, due to the collections of lymphoid cells already described. Occasionally the retina is irregularly thickened, so that the vessels present conspicuous antero-posterior curves. These changes constitute the ‘leukemic retinitis’ of Liebreich. The extent to which sight is interfered with depends on the degree to which the neighbourhood of the macula lutea is involved. The skin is strikingly pale, or sometimes, as already stated, greenish yellow. Occasionally a peculiar dark pigmentation is present. Sweating is common.

COMPLICATIONS.—The most frequent complications of leucocytthemia are pleural effusion, œdema of the lungs, lobar pneumonia, bronchial catarrh, pericardial effusion, dilatation of the heart, venous thrombosis, cerebral hemorrhage, and fatty degenerations; and the more rare are cirrhosis of the liver; purpuchymatous degeneration of the kidneys, giving rise to the symptoms of subacute Bright’s disease; renal calculi; persistent or intermittent erection of the penis, the former probably due to thrombosis in the corpora cavernosa; œdema of depending parts; ascites; furuncles; and erysipelas. The various hemorrhages are rather to be regarded as symptoms of the disease than as complications.

DURATION.—Cases of splenic leucocytthemia vary in duration from six months to seven years.

One or two recorded cases ran their course in less than six months. The average duration of sixty-three cases was two years. The actual duration of the affection is probably longer than this, because the disease has often reached a considerable degree before the symptoms became troublesome.

CAUSES OF DEATH.—The most common causes of death in leucocythæmia are loss of blood, asthenia, diarrhoea, cerebral hemorrhage, pneumonia, and pleurisy. In asthenia the actual end is often due to cardiac failure. The hemorrhage most frequently fatal is from the nose, the next most frequent from the bowels.

PATHOLOGY.—The pathology of leucocythæmia is still involved in obscurity. We are imperfectly acquainted with the normal life-history of the blood-corpuscles. For a full discussion of the facts which have been ascertained, and the theories built upon them, the reader is referred to the writer's article on the disease in Reynolds' *System of Medicine*, Vol. v. It is only possible here to give a brief outline of the pathology of the disease which these facts and theories suggest. Recent researches make it probable that the red corpuscles arise from a transformation of the smaller lymphoid cells—*globulins* of Donné, hæmatoblasts of Hayem—and that this transformation takes place to a large extent in the splenic pulp and in the marrow of bones, tissues which have many histological characters in common. If these tissues are diseased, the transformation may not take place, and the unchanged lymphoid cells may develop into the ordinary leucocytes, which are either retained in these tissues, increasing their bulk and changing their structure still further, or pass into the blood. Both results probably occur. Hence we assume a primary change of the splenic pulp, which is increased further by the retained leucocytes. Where the hæmatoblasts arise, is still uncertain—they are probably in part developed in the splenic pulp and marrow of bones from pre-existing cells, and from the protoplasmic trabeculae of the tissues (Klein); probably in part they come from the true lymphatic structures, the glands, Malpighian follicles of the spleen, &c. Primary disease of these lymphatic structures constitutes lymphadenoma; and the splenic pulp may be normal, and the leucocytes are only in slight excess, or are not more numerous than they should be. In true splenic leucocythæmia the glands and Malpighian follicles are not primarily diseased, but they may suffer secondarily, when lymphatic growths arise in organs; and this secondary affection is in part the result of the accumulation of leucocytes. That the enlargement of the spleen is not, as has been thought, merely the result of the accumulation in it of pale corpuscles from primarily diseased blood, is shown by the increased consistence of the organ, and by the fact that the splenic tumour precedes the change in the blood. There is some reason to believe that as the spleen alone may be diseased, so, in some rare cases, the marrow of bones may alone be diseased, and may give rise to a primary 'myelogenic leucocythæmia,' but this is not yet proved. That the disease may be primary in both the marrow and the spleen, is highly probable from recorded

facts. It is certain, however, that the marrow is, in most cases, not affected primarily, and may be unaffected throughout, or may suffer secondarily, as do the glands. The same is true of the collections of lymphatic tissue elsewhere in the body. The cases in which the lymphatic glands enlarge early—'lymphatic-splenic leucocythæmia'—are, for the most part, if not entirely, cases of composite nature. The spleen presents a double change—growth in the follicles, such as are associated with the glandular growths in lymphadenoma (Hodgkins' disease), and increase in the splenic pulp, as in pure splenic leucocythæmia. In such cases there may be a large increase in the pale corpuscles of the blood.

DIAGNOSIS.—The diagnosis of leucocythæmia rests on the existence of enlargement of the spleen, and a considerable excess of leucocytes in the blood. In all cases of splenic tumour, the blood should be examined; if the proportion of white corpuscles to the red is greater than 1 to 20, the case is certainly one of leucocythæmia. But if the proportion is less than this, leucocythæmia cannot with certainty be excluded, because it is probable that, in all cases, the splenic tumour and anemia precede the leucocytal excess, and the latter may be in process of development. To ascertain the actual state of the blood, it is always desirable to enumerate the corpuscles with the hæmacytometer. Repeated examination, to ascertain that the proportion of pale corpuscles is not increasing, is necessary before impending leucocythæmia can be excluded. In cases in which the lymphatic glands enlarge early, the question arises whether the case is one of splenic leucocythæmia, or of Hodgkins' disease. In the latter, as just stated, the enlargement of the spleen depends, not on an increase of the splenic pulp, but on overgrowth of the Malpighian follicles; the splenic enlargement is less than in leucocythæmia, and is less uniform. In the composite cases alluded to above, in which, with enlargement of the glands and splenic follicles (lymphadenoma), there exists also overgrowth of the splenic pulp, and a considerable leucocytal excess in the blood, the two morbid processes are conjoined, and the affection may be termed lymphadenosplenic leucocythæmia. These cases are distinguished from the simple splenic affection by the early enlargement and firmness of the glands. In simple splenic leucocythæmia the affection of the glands is usually late, and rarely considerable. The diagnosis of the disease from conditions in which a considerable excess of pale corpuscles exists, without enlargement of the spleen, is usually easy, because such excess is transient, soon passes away, and is not associated with a splenic tumour.

PROGNOSIS.—The prognosis of a disease which depends on a primary affection of the blood-forming organs is necessarily most grave. No means of arresting the progress of the developed disease has yet been discovered. The immediate prognosis is less serious in proportion as the evidence of organic changes in the blood-forming organs is slight, and in proportion to the early stage of the disease. Neither age, sex, nor constitution affords prognostic information. The greater the number of white corpuscles and the deficiency of red, as ascertained by counting, the worse the

prognosis. The size of the spleen, alone, affords little information. Hemorrhages are of grave augury, but epistaxis least so.

TREATMENT.—The knowledge of the causes of leucocythæmia, slight though it is, suggests important prophylactic measures—the prevention of ague, and the careful treatment of all who have been exposed to malarial influences. Splenic tumours resulting from such exposure should be systematically treated; the subjects of them should exercise great care to avoid exposure to cold, injuries, and all causes of portal congestion. These precautions are especially necessary in women at the menstrual periods; and if such women bear children, their state during pregnancy and after parturition should be carefully supervised, and lactation prohibited. Whether there is simple anæmia or leucocythæmia, every effort should be made to reduce the size of the splenic tumour, by quinine, cold affusion, ergotine, and especially by voltaic electricity, a most powerful agent. By obtaining contraction of the spleen, expelling retained leucocytes, and perhaps stimulating directly its functional action, we render its condition less abnormal. In a case of anæmia splenica no remedies improved the blood-state till the spleen was galvanised, when the red corpuscles at once began to increase. Remedies which do good in ordinary anæmia have slight influence in this disease. Iron is almost useless; cod-liver oil, how ever, has seemed to do some good. Arsenic has been largely tried, but without benefit in pronounced cases. Its undoubted value in lymphadenoma suggests its further trial in early cases; it should be given in the largest doses that can be borne. Phosphorus has been recommended, but in almost every case of pronounced leucocythæmia it has been powerless for good. Nevertheless, its influence in improving the blood-state in lymphadenoma warrants further trial in the early stage of the disease. Iodides, bromides, and mercury are useless. Change of air may slightly improve the patient's state, but has no influence on the disease. Transfusion has been tried, but the results are not encouraging. Excision of the spleen has been suggested. The operation has been performed with success in cases of anæmia splenica, but in actual leucocythæmia the operation has been invariably fatal—in most cases from uncontrollable loss of blood, the result of the hemorrhagic tendency. Further trial of it, in such cases, is not justifiable. In early cases, where there is no considerable excess of pale corpuscles, and the red are not reduced below sixty per cent. of the normal, it might be successful; but it is questionable whether, in such cases, the ultimate issue without interference is sufficiently certain to justify the performance of so grave an operation. Special symptoms may require treatment. Hemorrhages must be checked by the usual methods, and crystals of perchloride of iron may be applied to accessible places (Jenner). For vomiting, a posture which will relieve the stomach from pressure, and counter-irritations are useful. Aperients should be employed with caution; and under no circumstances should the yellow tint of the skin lead to the use of opiate. For the edema, digitalis and other diuretics are best. For the splenic pain, counter-

irritation, sedative liniments, and hypodermic injections of morphia may be used. In proportion to the anæmia, physical rest is important, that the diminished supply of oxygen may not be rendered inadequate for the need of the tissues, by muscular exertion. W. R. GOWEN.

LEUCOCYTOSIS (leucids, white, and *cytos*, a cell).—A condition of the blood, in which the white corpuscles are appreciably but moderately increased. See *Bigou*, *Morbid Conditions of*.

LEUCODERMA (leucids, white, and *derma*, the skin).—White or achromatous integument. See *PIGMENTARY SKIN-DISEASES*.

LEUCOMA (leucids, white).—A white opacity of the cornea, generally referable to inflammation or ulceration of that structure. See *EYE AND ITS APPENDAGES, DISEASES OF*.

LEUCOPATHIA (leucids, white, and *pathos*, a disease).—*SYNON.*: Albunism. Achroma, Leucoderma, Leuce, Leucismus.

This disease is sometimes general, but frequently partial; in the latter form constituting *cutis variegata* and 'piebald skin'. The whiteness is referable to absence of pigment, which may be simply due to an arrest of function of the rete mucusum, or to an organic alteration of the integument. See *PIGMENTARY SKIN-DISEASES*.

LEUCO-PHLEGMATIC TEMPERAMENT. See *TEMPERAMENT*.

LEUCORRHEÆA (leucids, white, and *rhoi*, I flow).—*SYNON.*: Fr. *Leucorrhée*; Ger. *Weisser Fluss*; Lat. *Fluxus Albus*, 'Pop. 'The Whites'; 'White Discharge.'

DEFINITION.—A non-hæmorrhagic discharge, of pale colour, escaping from the female genital fissure.

ÆTIOLOGY.—Leucorrhœa is a symptom rather than a distinct disease, and is found resulting from all the morbid processes that lead to hyper-secretion from the genital mucous surfaces, or from the glands opening upon them, whether the mucous membranes be injured or entire. It is, however, a source of much discomfort and deterioration of health, and so demands special treatment.

SYMPTOMS.—Leucorrhœa presents several distinct varieties according to the seat of its cause; and the symptoms of each variety require separate consideration.

1. **Vulvar Leucorrhœa.**—In this variety a glairy viscid secretion is found bathing the apposed surfaces of the pudenda, stiffening into a crust on the surface of the labia majora or on the insides of the thighs, and sometimes gluing the lips more or less firmly together at their margins. It is usually derived from the muciparous glands covering the internal surfaces of the labia majora and the nymphæ, but in cases of special eruptions and general vulvitis it may come from the vestibular surface; and in still rarer cases it is poured out from the glands of Barthelin. Vulvar leucorrhœa is met with at any period of life, but is most common in the young, *infantile leucorrhœa* almost always being of this variety. In cases of gonorrhœal infection

in the female, the vulva is usually the seat of a profuse discharge that is apt to become purulent, but it is rarely confined to this situation, spreading both into the urethra, and upwards into the higher spheres of the genital mucosa.

2. Vaginal Leucorrhœa.—The discharge in cases of vaginal leucorrhœa is most frequently white in appearance, of acid reaction, and due to a secretion from the general surface of the vaginal mucous membrane. Its whiteness, on microscopic examination, is found to be owing to the presence of quantities of scaly epithelial cells, many of which are crowded with fatty particles, whilst others have been quite dissolved in consequence of the fatty degeneration. Sometimes the discharge has a more yellowish tint, and then it is found to contain quantities of pus-cells among the epithelial scales. In the former group of cases we have to do with a simple catarrhal condition of the vaginal mucosa; in the latter there are red granulation-like spots scattered over the membrane, which has here lost its epithelial covering. Vaginal leucorrhœa is a complaint to which women are especially liable during their reproductive life. The catarrhal form is extremely common in young married females, whilst the other form occurs rather about the menopause, or, if occurring earlier, is complicated with some of the other varieties of leucorrhœa. Apart from specific causes, it may be brought on by sexual excesses; by the presence of a foreign body, such as a pessary; by a displaced uterus; by a chill; or by any condition that interferes with the circulation in the pelvis. In a large proportion of cases it is secondary to the next variety of leucorrhœa.

3. Cervical Leucorrhœa.—The discharge that comes from the canal of the cervix uteri is transparent, like unboiled white of egg, very tenacious, and of alkaline reaction. It may still present these characters as it escapes from the pudenda, but it generally becomes somewhat clouded as it passes through the vaginal canal, and gets acted upon by the acid secretion from the vaginal walls. Independently of this change in the vagina, it is sometimes found already more or less opaque as it lies within the cervical canal, and may be seen of a yellowish or greenish or reddish tint in various cases. The clear cervical leucorrhœa is seen under the microscope to be made up of a viscid magma, having entangled in it large numbers of columnar epithelial cells, which have a tendency to arrange themselves in rows. These are easily seen to be the ciliated epithelial cells that cover the normal mucous membrane, but deprived for the most part of their cilia. They are accompanied by smaller rounded cells like mucous corpuscles or wandering cells, partly derived from the interior of the crypts, and partly shed from the general surface from which the epithelium has been removed. In almost all cases some of the epithelial cells and mucous corpuscles are charged with fatty particles, and surrounded with granules, resulting from the breaking down of some of their number. The more turbid the fluid, the more the cells are found to have undergone such degeneration; and where the discharge is profuse, fluid, and of a yellowish colour, it has more the characters of a purulent fluid in which the relatively few cylin-

dric cells are changed in form, becoming oval or rounded, and nearly all reduced to a compound granular mass. The more deeply tinted discharges owe their discoloration to the admixture of blood, the red corpuscles of which can easily be recognised. Apart from the leucorrhœas of specific origin, this is the commonest of all the varieties. It may be found in females of any age, but specially affects women during their reproductive history, and more especially those who have been mothers. We can understand the special liability of the cervix to catarrhal affections, when we remember that all intra-uterine discharges pass through and may irritate it; that it is exposed to damage during the transit of the foetus in parturition, that vaginal affections easily pass into it by continuity of structure; and that it may readily be injured by foreign bodies in the vaginal canal, or even by fretting of its orifice against the vaginal wall in cases of displacement or excessive mobility.

4. Intra-uterine Leucorrhœa.—Here also the discharge is transparent, like white of egg, and alkaline in its reaction, but it is more fluid than the secretion from the cervical canal, and may escape as a clear liquid from the genital fissure. In cases of long standing, more particularly where there exists some organic disease in the uterine parietes, the fluid becomes turbid, purulent, and more frequently than in any other variety of leucorrhœa tinged with blood, even alternating with irregular discharges of blood. Under the microscope we see many cylindrical epithelial cells, not infrequently ciliated; along with groups of smaller cells, partly cylindrical, partly rounded, that have been discharged from the uterine follicles, all imbedded in a mucous fluid. Where the discharge is more turbid, the epithelial cells are seen to be undergoing fatty degeneration, and to be accompanied with wandering cells, pus-globules, and crowds of free fatty particles. This uterine leucorrhœa may be found at any period of life, but as an independent affection it is found almost exclusively in virgins or young married women, or in women who are ceasing, or have ceased, to menstruate. In the last-named class of cases the cervix is often atrophied, and its orifices narrowed; and the intra-uterine secretion may accumulate for a time, and be expelled with some degree of suffering. Most frequently it is found associated with cervical leucorrhœa, the endo-cervical affection having passed up to the endometrium, or, more rarely, *vice versa*. Perhaps the most frequent form of it is found in women who are subject to a leucorrhœal discharge before or after the menstrual periods; and in the cases of amenorrhœa where a pale discharge escapes at the usual menstrual periods, this has its source in the interior of the uterus proper.

5. Tubal Leucorrhœa.—Doubtless some small portion of the fluid that escapes in certain cases of leucorrhœa is furnished by the Fallopian tubes, but despite the elaborate attempts of Hænnig and others to establish a distinction between it and the other varieties, it remains rather as a subject of pathological interest than of clinical importance, and need not occupy us further here.

DIAGNOSIS.—The statements of a patient in regard to a leucorrhœal discharge cannot be re-

led on in establishing a diagnosis as to its source. If it be white and flaky we may judge that it is vaginal; if more transparent, and escaping in half-coagulated flocculi, we may conclude that it is cervical; whilst a clear and more continuous and fluid discharge would be more justly referred to the uterus proper. But it is never safe to trust merely to the appearance of the discharge as it escapes from the vulva, for it may have become modified as it lay in or traversed some part of the canal, or may be compounded of fluids derived from different surfaces. The seat of the discharge must therefore be exposed. In the vulvar variety it suffices to separate the labia and occasionally to expose the navelar fossa and the orifices of the Bartholinian ducts, by passing the finger into the anna. The vaginal form of leucorrhoea requires for its detection the use of a speculum, duck-bill or tubular; and the cervical, one of these or a bi-valve speculum. For the diagnosis of intra-uterine leucorrhoea it is sometimes helpful to remove some of the fluid for microscopic examination by means of a fine syringe. Unless a clear history of infection can be obtained, it is almost impossible to establish a distinction between a gonorrhoeal discharge and the simpler catarrhal leucorrhoea. In the former there is a very notable tendency to spread through all the contiguous mucous surfaces, though the vulva may be predominantly affected. In children suffering from the infectious discharge, traces of the injuries that are usually inflicted at the period of infection should be sought for.

TREATMENT.—In instituting our treatment of leucorrhoea it is of the first importance to have in view the *constitutional* condition of the patient; to use means to counteract any diathetic tendency—tuberculous, strumous, or syphilitic; and to raise as far as possible the general standard of the patient's health, by the administration of tonics, and the enforcement of a suitable diet and regimen. It is partly in this way that a change of residence is often useful; and in making a change, it is well for the patient to go to some of the spas, such as Ems or Kissingen, the waters of which are helpful in reducing congestions and catarrhs of the pelvic viscera. In young women of relaxed habit of body, it may be enough to prescribe quinine and iron or arsenic, and the daily use of a cold sponge bath; and in infantile leucorrhoea, cod-liver oil and iodide of iron should be administered.

In the great majority of cases of leucorrhoea, some kind of *local* treatment becomes an absolute necessity. Sometimes it is enough to pay strict attention to cleanliness, washing the pudendal surfaces with a soft sponge, or syringing the vaginal canal with tepid water; and even when astringent applications are to be made, the surfaces should first be subjected to a detergent stream of water. Where there is marked congestion of the uterus it is best to make the injections with hot water, and to keep the stream passing through the vagina for at least five minutes at a time; the immediate relaxation of the blood-vessels and hyperaemia being followed by contraction of their walls, which favours the cessation of the discharge. The astringents most serviceable for checking *catarrhal* and *vaginal* leucorrhoea are alum, sublimated iron, acetate of lead, sulphate of cup-

per, sulphate of zinc, borax, and infusions of oak-bark, matco, and other vegetables charged with tannin. They are best applied in the form of an injection with a Higginson's syringe, having a vaginal nozzle attached to it; or often douche through a long india-rubber tube, with a stop-cock for regulating the flow fitted close to the vaginal nozzle, and the other extremity opening into a wide receptacle, or fitted to a filler into which the fluid is poured. Where there is a difficulty in using the injection, and where it is desirable to keep up a more prolonged application of the medicament, it may be introduced into the vagina in the form of pessaries made with cacao-butter or with gelatine. Topical applications to the canal of the cervix and cavity of the uterus ought always to be made through the speculum, and without such applications it is a hopeless task to undertake the cure of *cervical* leucorrhoea. Here, more concentrated or more powerful astringents or escharotics become necessary. Nitrate of silver in the form of a stick of caustic is easily applied, but its repeated application may lead to mischief. Zinc-alum, dried sulphate of zinc, sulphate of copper, perchloride of iron, or tannin may be introduced in the form of rods or arrows made with starch and gum. If a uterine sound or stilette be dipped in water and a thin film of cotton wadding wrapped round the point to the length of about two inches, the adherent mucus can be cleared away, and the same or another sound mounted with wadding can be charged with fuming nitric acid, or the acid nitrate of mercury, or strong carbolic acid, or a solution of perchloride of iron, or tincture of iodine, and carried through the speculum along the cervical canal. In *intra-uterine* leucorrhoea it becomes necessary to carry the application right up in the same way to the interior of the uterus. It is usually best to begin with one of the stronger liquids, apply it a few days after a menstrual period, and follow it up with applications of iodine. So long as the stilette or sound with the dry wadding passes easily through the os internum, it is usually necessary to continue from time to time the intra-uterine application.

LEUKAEMIA. See LEUCOCYTHAEMIA.

LEUTERBAD (LOCITE), in Switzerland. Thermal earthy waters. See MINERAL WATERS.

LICE, Diseases due to. See PEDICULUS.

LICHEN (Λιχην, an eruption).—This term was originally assigned to lichens of the vegetable kingdom from the idea, which is by them suggested, of adhesion to the bark of a tree. Subsequently the term became transferred to a diseased state of the skin, but the precise nature of that disease is unknown at the present day. The affection which most nearly realises the signification of the term is *lepra vulgaris*, or possibly a centrifugal cluster of papulae. In the latter sense the term was adopted by Willan, and since his time it has been generally accepted as the type of a papular eruption of the skin. With this acceptation lichen is a folliculitis attended with prominence in the form of a minute pimple; and may be associated with eczema—as in the

Instance of lichen simplex, lichen circumscriptus, lichen agrius, and lichen tropicus; or with urticaria—asin lichen urticatus. It may, however, be independent of these, as in lichen pilaris, lichen planus, and the eruption described by Hebra, under the name of lichen scrofulosorum. See APPENDIX. ERASMUS WILSON.

LIENTERIC (*Æter*, smooth, and *Enter*, the intestine).—A form of diarrhoea in which the stools contain much undigested food, in consequence of its having passed rapidly along the alimentary canal. See DIARRHOEA; and STOOLS.

LIGHTNING, Effects of.—The effects produced by lightning differ only in degree from those produced by the discharge of static electricity, generated in the laboratory. With a Leyden jar of sufficient size a small animal may be killed, and in larger animals the effects of shock and local injury may be produced. By lightning a person may be killed outright, and a post-mortem examination may reveal no lesion whatever. The mode of death in these cases seems to be by the shock to the brain and nervous system generally. Effects not distinguishable from ordinary concussion of the brain may be observed, and the person struck may remain insensible, with slow respiration, scarcely perceptible pulse, and dilated pupils, for periods varying from a few minutes to more than an hour. This may be followed by complete recovery; or there may remain paralysis of the limbs, usually the lower, or occasionally derangements of the special senses—blindness, a metallic taste in the mouth, noises in the ears, and an odour in the nose. The brain may be more or less permanently affected, and we read of delirium, mania, and loss of memory as results of the lightning-stroke. Various objective phenomena have also been observed. The electricity on its way through the body may produce a number of mechanical effects. Wounds like those produced by a blunt stabbing instrument may mark the points of entry and of exit; bones have even been broken, the membrana tympani has been ruptured, and internal viscera have suffered in a similar way. Patches of erythema, urticaria, superficial oedymatous, and scorplings of the surface having a curious tree-like and branched arrangement, have all been described, and this last phenomenon has apparently given rise to the assertion that delineations of trees standing in the neighbourhood of the accident have been traced photographically on the body of the victim. Lightning is apt to be attracted by any metal worn about the body. Watch-chains are frequently broken and fused, and by the intense heating of these metallic conductors the clothing has been set on fire. Watches have been broken and partially fused, and have forcibly burst through the pockets in which they were contained. Steel articles, such as pocket-knives, have been rendered magnetic. The clothing is sometimes burnt and torn to a great extent, and strong boots have been found burst open, or thrown off the feet to a distance, or nails in the soles have been driven out of them. The remote effects of lightning are due to the mechanical injuries produced by it: permanent paralysis may result from injury to the nerves, and inflammatory

action may be set up by the injury inflicted on internal or external parts. One case is recorded in which the whole of the hair on the head and body, as well as the nails of both hands, came off after a lightning stroke. It has been asserted that *rigor mortis* does not occur in persons killed by lightning, and that the blood remains fluid for a very long time after death, but neither of these facts has been substantiated.

TREATMENT.—The treatment of those who have been struck by lightning consists in first rousing and keeping up the respiration and circulation. The cold douche is often of great value, and this combined with friction of the limbs, warmth to the extremities, and the administration of stimulants, either by the mouth or in the form of enemata, would seem to be the measures best calculated to restore the suspended animation. Secondly, special injuries must be subsequently treated according to their nature.

G. V. POORE.

LINÆE ATROPHICÆ (Lat. *Atrophie lines*).—A form of scleroderma. See SCLERODERMA.

LIPOMA (*lipos*, fat).—A fatty tumour. See TUMOURS.

LIPSPRINGE, in Germany.—Earthy waters. See MINERAL WATERS.

LISBON, West Coast of Portugal.—Warm, moist climate, with very variable temperature. Mean temperature in winter, 54° Fahr. Prevailing winds, N.E.—S.E. in spring; S.W. rainy. See CLIMATE, Treatment of Disease by.

LISDOONVARNA, in Ireland.—Sulphur waters. See MINERAL WATERS.

LITHIASIS. LITHIC ACID DIATHESIS (*Alēos*, a stone). See GOUT, and URIC ACID CALCULUS and DIATHESIS.

LITHONTRIPTICS (*Alēos*, a stone, and *triptis*, friction).—SYNON.: Fr. *Lithontriptiques*; Ger. *Stenaufloesende Mittel*.

DEFINITION.—Lithontriptics are therapeutical measures used for the purpose of dissolving calculi in the urinary tract.

ENUMERATION.—The chief lithontriptics are: Water, Potash, Lithia, Borax, Phosphate of Soda, Soap, Lime-water, Nitric Acid, Phosphoric Acid, Hydrochloric Acid, Sulphuric Acid, and Mineral Waters, such as those of Wildungen.

ACTION.—Lithontriptics dissolve stone in various ways. Some of them possess a simple solvent action, as in the case of water. Others unite with the calculi so as to form a more soluble compound, as in the case of the union of potash or lithia with the uric acid of a calculus, producing urate of potash or lithia, which is more soluble than uric acid itself. In the case of phosphatic calculi dilute nitric acid combines with the bases of which they are composed to form a more soluble compound.

USAGE.—Lithontriptics may be employed for the purpose of dissolving calculi either in the kidney or in the bladder. They may either be taken internally, so as to act upon the calculi through the medium of the urine; or be injected directly into the bladder. This latter treatment can only be adopted in the case of a vesical cal-

culus, and is inapplicable in the case of a renal calculus. The most useful of all lithontriptics is water, and especially distilled water. When this is taken in large quantities, the urine becomes very dilute, and small calculi may be partially dissolved, so as to be reduced in size and ejected through the natural passages. If the calculus is composed of uric acid, potash or lithia is the best remedy for internal administration, the urates of these bases being more soluble than the urate of soda. In the case of phosphatic calculi, acid remedies are employed instead of alkaline; but it is exceedingly difficult to render the urine acid by means of acids given by the mouth, unless they are administered in quantities likely to derange the digestion. In place of mineral acids, benzoic acid and benzoate of ammonia have been employed, as benzoic acid passes out of the body in the form of hippuric acid, giving an acid reaction to the urine. On account of this difficulty, acids have been directly injected into the bladder, in order to act directly upon the stone, for which purpose nitric acid, largely diluted, is the one which has been most generally employed. This procedure, however, is now rarely had recourse to, as it is much easier to crush the stone by mechanical means.

T. LAUDER BRUNTON.

LITHURIA (*lithes*, a stone, and *ōpōr*, the urine).—A condition in which a deposit of uric acid or urates takes place in the urine. See URIC ACID CALCULUS and DIATHESIS; and URINE, Morbid Conditions of.

LIVER, Diseases of.—SYNON.: Fr. *Maladies du Fois*; Ger. *Krankheiten der Leber*.

The liver is an organ which has always occupied a prominent place, both with the profession and the public, as being the seat of important diseases, as well as the origin and source of numerous symptoms and ailments. Not only is it concerned in the formation of one of the principal secretions, namely, the bile, but, according to most physiologists, it has a peculiar *glycogenic* function; and some authorities now maintain that it is in this organ that urea is formed. Moreover, a large quantity of blood passes through it, in connection with the portal circulation, by means of which the blood returning from the stomach, intestines, pancreas, and spleen is distributed throughout the liver, and thence conveyed to the inferior vena cava. Hence, hepatic affections, by interfering more or less with the physiological functions or anatomical arrangements of the organ, may give rise to diverse phenomena, not only of a local character, but associated also with the general system.

SYNOPSIS OF DISEASES.—The individual affections of the liver will be treated of separately, in alphabetical order, but it may be well to indicate here beforehand their general nature. The first great division is that into *functional* and *organic*. *Functional* hepatic disorders are regarded by many eminent physicians as being of peculiar significance, and as demanding special attention, particularly with reference to those disorders which influence the secretion of the bile. The *anal, organic* diseases of the liver, in which there is some more or less obvious anatomical change,

may be summarised thus:—1. *Obstruction*, either active or mechanical. 2. *Hæmorrhage* into the organ, or so-called *apoplexy*. 3. *Acute inflammation*, usually terminating in *abscess*, rarely in actual *gangrene*. 4. *Chronic inflammation*, ending in the condition termed *cirrhotis*, in which the liver is hardened, granular, and usually contracted. 5. *Hypertrophy*. 6. *Atrophy*, either *acute*—which is a very fatal disease; or *chronic*, the latter being of different kinds. 7. *Biliary accumulation*. 8. *Malposition*, and *malformations*. 9. *Infiltrations*, including *fatty* and *albuminoid* diseases. 10. *New growths*, especially *hydatids*, *syphilitic* formations, and cancer. Tubercle is occasionally found in the liver.

ÆTIOLOGY AND PATHOLOGY.—Taking a general survey of the causes which originate hepatic diseases, and of the circumstances under which they arise, the most important may be indicated thus:—1. An affection of the liver may be merely a local manifestation of some constitutional or general malady, as in the case of cancer, tubercle, syphilis, or albuminoid disease. The last-mentioned is remotely due to causes which need not be discussed here; but it may be mentioned that the liver is an organ very liable to suffer from albuminoid change. 2. Some local injury or irritation may originate hepatic disease, either from without, as a blow or stab; or from within, as sometimes happens in the case of biliary calculi. 3. Certain animal parasites entering the body are prone to lodge in the liver. This applies especially to *hydatids*, originating from the *Læna echinococcus*. 4. From the intimate connection of the liver with the alimentary canal, and the existence of the portal circulation, hepatic disorders are very liable to arise from improper diet, as well as from digestive derangements in the stomach and bowels, and constipation. 5. Abuse of alcohol, and especially indulgence in ardent spirits, occupies an important position in the ætiology of disorders and certain diseases of the liver. Undue use of hot condiments is also regarded as an element of some consequences. 6. Long-continued exposure to a high temperature in tropical climates is a powerful cause of hepatic derangement and disease, particularly if accompanied with too free indulgence in alcoholic stimulants. 7. Diseases of the liver may arise by extension from neighbouring structures, or by the convection of morbid materials from more or less distant parts. The latter may be best illustrated by pyæmia; and secondary affections of this kind are believed to be particularly frequent in the liver, when the morbid products are conveyed directly from the alimentary tube, in consequence of some disease of its walls, such as ulceration. 8. Obstruction to the circulation, due to certain forms of cardiac disease, is an important cause of some hepatic affections. 9. Disorders of the liver are often attributed to various hygienic errors, exposure to cold, and other causes, but how far this conclusion is justified in particular cases is a matter of question.

CLINICAL SIGNS.—So far as the actual diseases of the liver are concerned, it is unnecessary here to regard any symptoms resulting from disturbance of the glycogenic functions, as these belong to a different category. The clinical phenomena to

be looked for lie within a limited range, and may be grouped under the following heads:—

1. *Morbid sensations*, referred to the hepatic region, of to the shoulder, such as pain of various kinds, tenderness, sense of weight, throbbing. 2. *Symptoms due to interference with the biliary functions*, particularly jaundice and its accompanying phenomena. 3. *Symptoms resulting from more or less obstruction to the portal circulation*. These include digestive disorders, due to congestion or catarrh of the mucous membrane lining the stomach and intestines; hæmorrhage from this membrane in some cases; ascites, which is a most important symptom, enlargement of the spleen; congestion of the womb in women; hæmorrhoids; and, in certain conditions, dilatation of the veins of the abdominal wall. 4. *Symptoms produced by the pressure, or interference with neighbouring structures, of an enlarged liver*. Thus, it not uncommonly extends upwards, checking the movements of the diaphragm, and pressing upon the lung, hence causing dyspnoea. Or it may compress vessels and other structures, or in some cases it even interferes with the heart's movement. 5. *Physical signs*.—These indicate enlargement or contraction of the liver; changes in situation or shape; or changes in physical characters. 6. *General symptoms*. These may be more or less independent of the hepatic disease, this being merely a part of a general malady; or the liver-affection may give rise to pyrexia, wasting, and other symptoms. Hepatic derangements are supposed to originate many general symptoms, not obviously connected with this organ, and they have even been made accountable for the gouty state.

The individual diseases of the liver will now be discussed in alphabetical order.

FREDERICK T. ROBERTS.

LIVER, Abscess of.—*ΣΥΝΟΧ.*: Hepatic abscess; *Fr.* *Abscès du Foie*; *Ger.* *Lehrabscess*.

Though of such importance as to require a separate notice, abscess of the liver is not an independent affection, but is only the consequence of inflammatory action set up in that organ.

ÆTIOLOGY.—As abscess of the liver is comparatively rare in temperate climates and frequent among Europeans in tropical ones, it has naturally been attributed to the effects of heat, or of alternations of heat and cold. Being occasionally associated with malarious fever, and frequently with dysentery, it is supposed that it may be induced by the same causes as those diseases. The opinion has been often advanced that abscess of the liver is always secondary to dysentery, or to ulceration of the bowels. That it may occasionally be so it would be difficult to deny, with reference to what is known of its occasional causal connection with operations on the rectum. But although dysentery and hepatic abscess are frequently associated, this association is very rare except in the tropics; nor is it there very constant. Thus dysentery is extremely common in children, while abscess of the liver is equally rare among them; indeed, abscess of the liver is very unusual under the age of twenty, and is more common after the age of twenty-five than below it. The proportion of cases in which

liver-abscess and dysentery are associated is extremely variable; it is more frequent in one year than in another, and also at one period of the year than at another. Although dysentery is the commoner affection, yet occasionally the number of cases of hepatitis, with a certain proportion of deaths from abscess, may greatly exceed the number of cases of dysentery. There are many fatal cases of abscess in which the bowels have been found perfectly healthy; abscess of the liver, on the other hand, can scarcely be considered to be very frequent in dysentery. Yet dysentery and abscess of the liver seem to arise in the tropics from very much the same causes; and something is there impressed on the constitution which seems to render the system, even for some years after a return to Europe, somewhat inclined to liver-abscess.

Abscess of the liver is an occasional result of pyæmia, and connected at times with surgical operations, especially with those performed on the rectum. It has been induced by falls or by direct violence; or by the impaction of a gall-stone, especially where it has been rough and spicular.

The *predisposing* causes are the same as those of hepatitis—drinking, irregular life, exposure, and residence in the tropics.

ANATOMICAL CHARACTER.—The course of formation of hepatic abscess seems to be the following.—The liver is first loaded in some portion or portions with an excess of blood; then follows exudation of lymph and pus, forming small deposits, of which two or three coalesce, while the liver-substance breaks down. The abscess extends in this mode. It is usually lined by a membranous cyst, which is very thin when the formation of the abscess has been rapid, and of greater consistence when the abscess is old. The abscess may be of almost any size, from that of a small orange up to a huge cyst containing ten or twelve pints of pus. Six hundred ounces of pus have been withdrawn from an abscess in five months. Most commonly the abscess is single, but frequently there are several abscesses. They are most common in the right lobe. They may have reached the surface or have burst, or they may be only discoverable on making an incision into the organ after death. In the great majority of cases, if the abscess has not been exposed to the air, its contents are laudable or healthy, inodorous pus. In some cases the pus is of the colour of chocolate. It is said that streaks of bile have sometimes been observed. Slight pinkish streaks are not so rare. An abscess may open through various channels. Sometimes it finds its way to the surface, and discharges itself through the skin. This usually happens lower down than the ribs. The abscess may open into the peritoneal cavity, and has done so into the pericardium. In such cases the result is fatal. It passes occasionally into some portion of the bowels, and as this causes the least constitutional disturbance, it is a favourable mode of discharge. Very frequently, when the abscess is near the convex side of the liver, the diaphragm and the surface of the liver become adherent—as in this case the abscess has not usually been very deep-seated—and the abscess opens itself through the lung. This often fails

chance of recovery. There are still other possible points of exit, but these are chiefly matters of curiosity.

When the abscess has burst, cicatrization commences, and has sometimes been traced when the case has terminated fatally. But it is remarkable that well-marked cases of complete cicatrization have not often been recorded—various membranous formations and slight depressions in the liver being now considered to be the results of syphilitic hepatitis. There is a strong presumption that liver-abscess is occasionally absorbed without having ruptured, and also that it may remain latent for a long period. In cases where the abscess has been partially absorbed, a white fibrous sac has been found, containing a little pus and sometimes cheesy matter; and in some cases in which there has been strong presumption that the abscess had existed for four or five years, the walls of the abscess have been found much thickened, and almost cartilaginous. Although a portion of the liver has been converted into abscess, the remaining portion of it may be healthy, or somewhat indurated from former attacks of congestion; and it is wonderful how in favourable cases, where the contents of an abscess have been absorbed or evacuated, the remaining healthy portion of the liver executes its work.

In addition to the formation of ordinary hepatic abscesses, suppuration may take place extensively throughout the liver, after lobular hepatitis, as in a case recorded by Dr. Quinn (*Path. Soc. Trans.* 1853), and also in the portal canals, or beneath the investing capsule of the liver.

SYMPTOMS.—These are more urgent when acute hepatitis runs into abscess, than when abscess is the consequence of repeated attacks of illness, as is most commonly the case. The general symptoms are a pale, muddy complexion; a look of anxiety, and a state of low, irregular feverishness, the pulse being generally about 100, and the temperature increased by a degree or two. There may be one or two shivering fits, or accessions of fever simulating ague. The appetite is impaired; there is vomiting, with irritability of the stomach; the tongue has generally a white coating, but in some cases is almost clean. The throbbing pain which usually accompanies the formation of pus is scarcely ever present. There is occasionally pain in the shoulder or shoulder-blade, but this is uncertain. A certain amount of pain, usually dull, is felt in the liver, often increased on pressure; attended with more or less, and sometimes with very considerable, enlargement of the organ. There is also fulness or bulging of the right side; and at the last, possibly, fluctuation. If abscess form on the upper side of the liver, there is more or less pressure on the diaphragm, causing shortness of breath, and occasionally leading to local inflammation, attended with acute pain. But such symptoms, which are more valuable taken collectively than individually, may not be present in a marked degree. The state of the biliary secretion is very often normal, or nearly so; and the condition of the urine affords no certain indication, although bile-pigment is sometimes present in it. Jaundice is comparatively rare. In some of its more in-

sidious forms, hepatic abscess may come on without being preceded by fever or ushered in by shiverings; but even in such cases a general falling off of the health is always observable.

As has been already pointed out, the abscess may burst in various directions; or it may be opened by a surgical operation. As a general rule the result is more favourable—probably because the opening being small the pus escapes gradually—when the abscess finds an opening for itself, than when it is evacuated artificially. In the latter case the discharge usually lasts for some months—nay, for more than a year in some instances; and although the patient improves up to a certain point, he is very likely to sink in the end. When the patient sinks, it is usually from general exhaustion of the system. Pyæmia is of extremely rare occurrence.

COMPLICATIONS.—Abscess of the liver is often complicated with dysentery, or with diarrhoea; and less frequently with malarious fever. Sometimes there is a certain amount of pleurisy or pneumonia. This is more frequent in acute cases than when the formation of abscess has been slow.

DIAGNOSIS.—A positive diagnosis is difficult to make in the early, and sometimes in the later, stages of hepatic abscess. The writer has known an iron-worker burst an abscess through his lungs when at work, the presence of which was not suspected, also a medical man submit his side to examination by several of his brethren, bear any amount of pressure, and yet die two days after choked by the bursting of an abscess. Nevertheless, an experienced physician will from the symptoms be able to guess the presence of abscess of the liver before any palpable signs appear. These are, first, the general aspect of the patient; then the enlargement of the side. It is only in a more advanced stage that fluctuation can be made out. As to the diagnosis after the abscess has burst, if it breaks through the lung the peculiar chocolate-colour expectoration is at once characteristic. If the abscess bursts into the pleura or peritoneum, the diagnosis is not so positive, but the sudden collapse usually shows what has happened. When the abscess bursts through the bowels, especially in small amounts at a time, the fact is rarely recognisable, except by the gradual improvement of the patient. It seems to be certain that hepatic abscess has sometimes been confounded with a distended gall-bladder: with care, however, such a mistake can scarcely happen. It may be confounded with cancer or with hydatids of the liver; but in these affections—and particularly in the last—there is very little constitutional disturbance, and in cancer a nodular protuberance may very generally be recognised. The only other mistake that is occasionally made is, that of confounding abscess and the effects consequent on its presence, when it points upwards, with pneumonia or pleurisy near the base of the right lung; but with careful auscultation the affection of the lung or pleura ought to be made out by their physical signs.

PROGNOSIS.—This is generally very unfavourable. Yet there is always a chance of recovery if the pus finds for itself an exit, as through the bowels or lungs, or even if exit to it is given

artificially. The statistics of the results of making artificial openings are not very encouraging. The operation, however, frequently appears to prolong life. The most favourable mode of exit is through the lungs. The discharge of pus may continue for six months, and yet recovery take place. Absorption of the abscess probably sometimes occurs, though this is a very rare termination. Such absorption is, obviously, chiefly a matter of inference. If a patient recovers from an attack of liver-abscess, his health may return to its usual standard. There is reason to believe that individuals have lived thirty or forty years after the occurrence of abscess; and the writer knew a man of 75, who had had abscess forty-five years before.

TREATMENT.—To avert the formation of abscess the ordinary treatment for hepatitis is the only one that can be adopted. When abscess has once formed, or even whenever there is good ground for suspecting this, the time for all active treatment has gone by. The patient must have his strength supported by mild nutritious diet and wine. He must be treated symptomatically. Usually it is sufficient to secure regular action of the bowels, and thus help the sound remaining portion of the liver to perform its function. Mineral acids, quinine, and other tonics, may all be useful. Counter-irritation over the liver is often tried, but it may be doubted whether in this condition of things it is a measure of any importance, although some think that it may help to limit the extent of the abscess. The course of the disease must be watched. The only mode of interference that we can pursue is that of helping to give exit to the contents of the abscess. Towards expediting this little can be done until fluctuation becomes evident, and then interference is to be delayed as long as possible, as nature will probably select the most convenient spot for the exit of the pus, and, after all, the presence of other undetected abscesses in the liver may make operative procedure useless. The abscess may point in an intercostal space, below the edge of the ribs, at the epigastrium, and even as low down as the umbilicus. A great deal has been written about modes of opening the abscess, and of ascertaining first whether it has formed adhesions, and various modes have been suggested for ensuring adhesions. However these are not matters of much practical importance. It is usual to make an opening whenever there is distinct bulging between the ribs; but it is better, when it is at all possible, to wait and operate, if it can be managed, below the ribs. However near the surface the abscess may appear to be, a lancet is seldom sufficient, and a good-sized trochar and cannula should be employed. The aspirator, and everything that will help to prevent the introduction of air, should be taken advantage of, and the precautions of the antiseptic method most strictly observed. For there is always a chance of gangrene after a time supervening round the opening, and the risk of this seems to be greater the higher up the opening is made. The evacuation of an abscess usually produces amelioration of the general condition, whether it be permanent or not.

Change of climate may operate favourably when the patient is suffering from the long-

continued drain of an open abscess; and if we are to judge by the number of patients suspected of having liver-abscess who have been sent to sea and who have arrived in Europe with their symptoms relieved, we may almost venture to say that a long sea-voyage under favourable circumstances assists absorption. In favourable cases the sequelae of liver-abscess must be treated like those of hepatitis. J. MACFARLAN.

LIVER, Albuminoid Disease of.—*STROM: Fr. Degeneration amyloide du Foe; Ger. Amyloide Entartung der Leber.*

DEFINITION.—A disease characterised by painless, more or less considerable, enlargement of the liver; due to the existence in its structure of a peculiar homogeneous substance, the exact nature of which is not known, but which has a marked relation to certain cachexias and constitutional maladies.

ETIOLOGY.—Albuminoid disease of the liver occurs in association with certain cachexias, especially those of constitutional syphilis, scrofula, rickets, scrofulous diseases of bones and joints, and other diseases attended with protracted suppuration. It has been noticed in connection with chronic dysentery, but the records of the Seamen's Hospital do not confirm such association. In many cases of chronic ague, with marked cachexia, which have been admitted into the hospital just named, there was an enlarged, hard liver, pointing to albuminoid change; but there was probably in these cases the superaddition of syphilitic taint. Rokitsansky speaks of the disease as congenital in children born of syphilitic parents.

ANATOMICAL CHARACTERIS.—The liver has its normal shape; is more or less enlarged, sometimes to such an extent as to fill the greater part of the abdominal cavity; and is hard, resistant, and inelastic, with a smooth glistening surface. The organ cuts like bacon, hence the name 'lardaceous.' The cut surface is grey, or fawn-colour, or pale red; but sometimes it is yellowish, and this appearance, in conjunction with the consistence of the organ, has led to the name 'waxy.' From the incised veins a little pale blood usually oozes. The application of solution of iodine to the cut surface causes change of colour, which has been described as blood-red, reddish-brown, mahogany brown, walnut, by different observers. The addition of sulphuric acid induces a blue colour, best seen in a delicate section placed under the microscope. Supposing a lobule of the liver to be divided into three zones, the characteristic iodine stain will be seen, in less advanced stages of the disease, to be limited to the middle zone, where the hepatic artery is distributed: the vessels and cells here being filled with the new material, which afterwards may extend so as to implicate the entire lobule. The structures invaded by the new material have, in a section examined microscopically, a lustrous, transparent, and somewhat swollen appearance. When the entire lobule is affected, the aspect is homogeneous. The appearance of an albuminoid liver may be modified by the co-existence of fatty change, or cirrhosis, or syphilitic disease. The spleen is generally, and the kidneys are occasionally, in-

planted. Cornil has used some new colouring matters, namely, two methyl-anilin violets, discovered by Lauth, and a violet discovered by Hoffman, as tests of albuminoid degeneration. The normal tissues of the liver and other organs do not decompose the violets, but when amyloid degeneration is present, the affected parts become of a violet-red, the normal structures assuming a violet-blue tint. In the examinations of specimens by Cornil the hepatic cells were unaffected, a result in opposition to generally received views, as just stated, and to his own previous investigations. In all cases the walls of the capillaries, or of the hepatic arteries and veins, were affected. Methyl-green has been more recently used for the same purpose.

SYMPTOMS.—Palpation, in marked cases of albuminoid disease of the liver, will readily detect a large, hard, resistant tumour, having the normal outlines of the liver; the smoothness of its surface; and the extent to which it encroaches upon the abdominal cavity. Pressure does not elicit any tenderness, nor is there usually any pain; at most, in advanced cases, there is only a sense of tension and fullness, as in other hepatic enlargements. The painless nature of the tumour is distinctive. The disease does not interfere with the portal circulation, and does not therefore directly cause ascites. When this occurs it is the result of general cachexia, induced by the constitutional malady, and perhaps by associated renal complication. The dropsy generally affects the legs in the first instance, and afterwards the serous cavities, and is not a prominent symptom unless the kidneys are implicated. In this case the urine is usually of low specific gravity and albuminous, and the anemia very marked. The system of bile-ducts not being obstructed by the disease, there is no jaundice; or if this occur, which is a rare event, it is from pressure on the duct externally by enlarged lymphatic glands. The evacuations are, however, frequently of a pale yellow, and at times of a clayey, colour, which may be accounted for by the extensive impairment of secreting structure, and the consequent secretion of a poor, colourless bile. A lardaceous state of the spleen is a frequent accompaniment of the liver affection, and gives rise to increased volume and hardness of the organ, which may be detected by palpation in the left hypochondrium. Vomiting, without the usual indications of gastric derangement, as furred tongue, &c., and diarrhoea, are symptoms not uncommon in advanced cases, and are due, according to Frerichs, to the implication in the disease of the vessels and villi of the stomach and intestines.

DIAGNOSIS.—The peculiar features of the enlargement, its painless character, the concurrence of the constitutional maladies already noticed, especially if with implication of spleen and kidneys, will distinguish this from other hepatic enlargements. If there be associated cirrhosis or syphilitic disease, the diagnosis will be difficult; but, as Hamberger remarks, an error will not be of moment as regards prognosis and treatment.

PROGNOSIS AND DURATION.—The disease may run on for months or even years, but it generally proves fatal, either by intercurrent infection or by anemia, general dropsy, and

exhaustion, such result being more rapidly determined when the kidneys are involved. In the early stage of the malady an arrest of mischief, if not a cure, may possibly be effected.

TREATMENT.—It is only in the earlier stages of albuminoid disease of the liver that treatment can avail, and then it must be directed especially to the associated cachexia. Whether this be syphilitic or strumous, the preparations of iodine are indicated; the iodide of potassium, the tincture of iodine, or, where the anemia is marked, iodine in combination with iron. The syrup of iodide of iron in drachm doses, three times a day, has proved useful, if not in reducing the tumour, at least in improving the general condition of the patient. The iodine mineral springs, as Woodhall Spa, Kreuznach, Adelheidsquelle, &c., are indicated, although they contain but infinitesimal doses of iodine and bromine. The baths of Aix-la-Chapelle, Ems, and Weilbach have each had their supporters in the treatment of this malady. Hydrochlorate of ammonia, in ten to twenty grain doses, three times a day, continued for some time, has been found to be efficacious in reducing large, hard livers (Budd, Begbie). The general therapeutical indications are pure air; plain, nourishing diet; the regulated use of alcoholic stimulants; and adequate protection of the skin by warm clothing and other measures. **STEPHEN H. WARD.**

LIVER, Apoplexy of.—By this is meant hemorrhage in the liver, in the form either of isolated patches of extravasation or of general effusion, the whole of the hepatic parenchyma being converted into a dark-red pulpy mass. This affection is rarely met with in this country, but has been often observed abroad in warm climates and malarious districts, as a result of disease of the liver, or prolonged and intense congestion. It occurs also in some cases of scurvy. Abercrombie believed that the puerperal condition predisposed to hepatic apoplexy. It has been observed also, according to Frerichs, in some new-born infants after long labours, and in cases of this kind it is usually associated with pulmonary atelectasis. A rapidly fatal case of hepatic apoplexy was reported by Audral, in which there were no indications of any efficient cause of the hemorrhage (*Clin. Méd.*, 3 ed., t. II., p. 289.) Extravasation of blood into the substance of the liver, together with a pulpy condition of more or less of the parenchyma, may be produced by the application of violence to the hepatic region.

SYMPTOMS.—The symptoms that have been observed in cases of hepatic apoplexy are pain in the right hypochondriac region, and excessive tenderness; jaundice; bilious vomiting; melæna; a cold and bloodless condition of the skin of the face and limbs; and in some cases syncope.

This affection is almost invariably fatal when due to prevailing disease of the liver, or to extensive laceration. **W. JOHNSON SMITH.**

LIVER, Atrophy of, Acute Yellow.—**SYNON.**: Fr. *Atrophie jaune aiguë du Foie*; *Jaître grave*; Ger. *Acute Atrophie der Leber*.

DEFINITION.—This is a general disease, likened by Trouessart to a pyrexia. The jaundice, being

so prominent a symptom, formerly drew attention too exclusively to the liver, but the same degeneration which seizes upon the liver, likewise attacks all the glandular and muscular organs of the body. The morbid change is a parenchymatous degeneration, called by Virchow and his school a parenchymatous inflammation. It consists in a filling of the cells of a gland with albuminous granules, in such numbers as altogether to hide the nucleus; the albuminous granules are quickly followed by oily particles and drops. In the muscular tissue, the striation is lost, and its place taken by granules, placed irregularly or running lengthwise. These morbid appearances are found in poisoning by phosphorus, arsenic, antimony, alcohol, and other agents, and in all fevers, though in a less degree than in acute yellow atrophy. Buhl was the first to point out that the pyrexial changes were the beginnings of acute yellow atrophy.

ETIOLOGY.—Acute yellow atrophy is perhaps the rarest of all the diseases common to this climate. Of its causes, next to nothing is known. It seems to be more common in women than in men; and in pregnant women than in others.

It has been shown that in pregnant and suckling quadrupeds and laying hens, the liver and kidneys often show cells infiltrated with fat, a fact which may throw some light on the disposition of pregnant women to acute yellow atrophy. Emotional disturbances, such as grief and trouble, and bad hygienic conditions, have been thought by some to predispose to this disease. Others believe that all cases may be traced to phosphorus-poisoning.

ANATOMICAL CHARACTERS.—After death it is not uncommon to find the liver of natural size, or even enlarged, in the early stages of acute atrophy. Later on the organ shrinks, so that in extreme cases it may weigh as little as nineteen ounces. It decreases in all diameters, but the left lobe is especially shrunken. The capsule is often wrinkled. On section, there is no longer any appearance of lobules, but an ochre-coloured surface without definite structure, but often reddened. Under the microscope, the liver-cells are found, in the early stages, to be filled with granules, so as completely to hide the nucleus, part of these granules are soluble in acetic acid, others are not. Later on, all trace of liver-cells may be lost, nothing but a granular and oily detritus and pigment being seen under the microscope. If the organ be set aside, it often becomes covered with crystals, stated by Frerichs to consist of leucin and tyrosin.

The spleen is enlarged and soft in the great majority of cases. The stomach and alimentary canal are filled with dark-red or tarry contents, the outcome of hæmorrhage; the tubular glands of the stomach are filled with fatty degenerated epithelium. The muscular tissue of the heart shows likewise fatty degeneration; and the tubules of the kidneys are filled with epithelium in various stages of fatty degeneration.

SYMPTOMS.—Acute yellow atrophy is commonly preceded for some days or weeks by a simple jaundice, in which nothing peculiar can be made out. Delirium and convulsions then suddenly set in, followed by deep coma, stertorous breathing, and dilated pupils. During the

first part of the disease the pulse is natural in frequency, but with the appearance of the convulsions and delirium it rises to 120 or 130. The skin is always yellow, rarely deeply coloured. The urine is natural in quantity, bilious, containing leucin and tyrosin, and towards the end of the disorder, containing no urea, chlorides, or phosphatic earthy salts; a kind of peptone is present. There is almost always constipation; the stools being at first pale, afterwards black from admixture of blood. Vomiting is very constantly present; at the end of the disease, of a black coffee-ground matter. The right hypochondrium and epigastric regions are painful and tender. The liver, at first natural in size, or even larger than natural, decreases daily in dimensions, so that at last percussion may give no liver-dullness at all. With the decrease of the liver, the spleen increases in size. A hæmorrhagic diathesis likewise sets in, as shown by petechiæ on the skin, epistaxis, hæmatæmesis and melæna. The temperature is commonly low, until just before death.

DIAGNOSIS.—The diagnosis is beset with difficulties, and may remain doubtful even after death. Poisoning by phosphorus can hardly be distinguished from acute yellow atrophy, unless the patient own to having taken the drug. The prodromal stage cannot be distinguished from simple jaundice.

PROGNOSIS.—The prognosis is extremely bad; only a very few suspected cases are known to have recovered.

TREATMENT.—The treatment must be conducted upon general principles. A few cases, in which the diagnosis of acute yellow atrophy has been thought justifiable, have recovered, and these have been treated with the mineral acids and purgatives, acetate, quinine, and camphor. These are therefore the remedies which may be recommended to be used. Local symptoms, such as vomiting or bleeding, must be treated as in other diseases. J. WICKHAM LING.

LIVER, Atrophy of, Chronic.—Chronic atrophy of the liver is seen in many wasting diseases, and in old age, the liver then often shrinks, becoming tougher in consistence, but rarely granular on the surface. The cut surface is dark red or pale brown, the acini are either invisible, or else smaller than natural. Frerichs thinks that the blood-vessels are all atrophied. The increased toughness seems due to the atrophy of the liver-cells, the meshes of the connective-tissue network being thus brought nearer to each other.

The symptoms of chronic atrophy are merged in those of the primary disease, against which all treatment must be directed.

J. WICKHAM LING.

LIVER, Biliary Accumulation in.—**ANATOMICAL CHARACTERS.**—When a permanent obstruction to the flow of bile into the duodenum has been set up, serious changes take place in the gall-ducts and the liver itself (see GALL-BLADDER AND GALL-DUCTS, Diseases of). At first the liver swells, apparently from the pasty secretion. It becomes of a deep bilious or olive-green colour, the central parts of the acini being the deeper coloured; on section the dilated

ducts are seen, and bile or a colourless fluid wells out of them. Increase in the consistence of the liver commences; and if the obstruction continues, the organ wastes, becomes much tougher, and shows a granular surface. This increase in consistence is due to an overgrowth of the connective-tissue of the liver, as in cirrhosis, only to a less degree. The amount of over-growth depends upon the kind of obstruction. It is greater when a rough angular gall-stone is the cause, than when an hydatid tumour with its smooth walls presses upon the gall-ducts. This over-growth springs at first from the gall-ducts, which are greatly thickened, and thence spreads over the connective tissue of the portal canals.

The liver-cells atrophy, as in cirrhosis. They vary much in size. Their contents seem to be chiefly fat and pigment-granules, though neither is of very great amount as a rule. The arrangement in rays around the hepatic venule is quite lost. One of the most important functions of the liver is the preparation of glycogen, and this function seems to be abolished in long-continued jaundice. In animals whose bile-ducts were tied, the writer found the glycogen to disappear not many hours after the ligature was applied; and after puncture of the fourth ventricle, no sugar appeared in the urine.

In some cases of complete obstruction to the bile-ducts, the liver-cells have been found altogether destroyed, nothing but a fatty detritus being seen under the microscope. This is not owing simply to *post-mortem* changes in the liver; but is possibly due to the long-continued action of the bile-acids circulating in the blood upon the liver-cells themselves, as Leyden has pointed out. It is not owing to the simple solution of the liver-cells in the bile, for the bile has not the power of dissolving these cells, as Th. von Dusch has asserted.

SYMPTOMS.—As regards the clinical phenomena of biliary accumulation in the liver, there are, of course, all the symptoms of jaundice and of the disease which leads to it. In addition, the liver at first swells, and may be detected below the ribs for two or three fingers' breadth, but rarely more; it is often painful on palpation. Later on, the liver retreats within the boundaries of the chest. Ascites often shows itself, owing to the disturbance of the circulation in the liver; and the spleen often swells. All these symptoms are, however, liable to be interfered with by the primary disease.

TREATMENT.—The treatment must be directed to the cause of the obstruction of the ducts.

J. WICKHAM LEOG.

LIVER, Cirrhosis of.—**SYNON.**: Granular liver; Hobnailed liver; Gin-drinker's liver; Interstitial hepatitis; *Fr. Cirrhose du Foie*; *Ger. Cirrhose der Leber*.

DEFINITION.—A chronic disease of the liver, in which the organ becomes hardened, and usually more or less diminished in size, at the same time assuming a granular or hob-nailed appearance; these changes resulting from an increase in the connective-tissue, usually caused by chronic inflammation. The name *cirrhosis* was first given by Laennec to the hardened

and shrunken liver, on account of the yellow colour of the granulations in this disease.

ÆTIOLOGY.—The most common cause of cirrhosis is, undoubtedly, the abuse of spirituous liquors. Spirits, unmixed with water, seem to be more potent in causing cirrhosis than wine or malt liquors. Next after these, but at a great distance, come syphilis, and the immoderate use, it is said, of spices—such as cayenne or coffee. In some rare cases no cause is apparent. The disease is far more common among men than women, it is very rare indeed amongst children. In one of these cases, the child asked the nurse for gin soon after admission into the hospital. *Cirrhosis* has also been seen among the lower animals, a proof that alcohol is not the sole cause.

ANATOMICAL CHARACTERS.—The seat of the disease in cirrhosis is the capsule of Glisson. The connective-tissue, which accompanies the vessels entering at the portal fissure, and which forms a covering for the liver beneath the peritoneum, takes on a very active overgrowth. One result of this overgrowth is a compression and atrophy of the secreting cells of the liver. Another is a hindrance to the flow of blood through the liver, for, although new vessels do indeed form in the new connective-tissue, yet these are by no means enough to carry on the circulation, in the place of those obliterated or destroyed by the advancing overgrowth of connective-tissue.

There are several varieties of cirrhosis. In the first—that which is most common—the liver is shrunken, it may be to one-half or one-third of its natural size. This shrinking is often greatest in the left lobe, so that this may become a mere appendage to the right. At the sharp edge of the liver, there is often nothing left but a semi-transparent tissue, containing none of the elements of the gland. False membranes often join the surface of the liver with the diaphragm or other neighbouring parts. The surface itself is greatly roughened. It shows numberless granulations, varying in size from a poppy-seed to a hazel-nut. The fibrous investment of the liver is greatly thickened, and the peritoneum tears off either in layers, or leaving a granular surface behind. The liver is exceedingly hard and tough; and on section, the cut surface is seen to be made up of yellow islets, imbedded in a white translucent tissue. These yellow bodies are the representatives of the granulations seen on the outer surface, and they are the remains of the natural liver-tissue, separated from one another by the new white connective-tissue. This is by far the commonest variety of cirrhosis, but there are others. One form is *hypertrophous* cirrhosis, in which the liver is greatly increased in size, sometimes more than double its natural weight; but the surface is smooth, and the capsule, though thickened, leaves a smooth surface when torn off. There is toughening of the liver, though not to so great a degree, and the same appearance of the cut surface as in ordinary cirrhosis. In another variety the organ is shrunken, but the surface is smooth, and on section are seen only pins' points of yellow tissue in the white translucent overgrowth. Whether the hypertrophous variety ever becomes shrunken is still undecided. A third variety is *fatty* cirrhosis, which may be

mistaken at first sight for fatty liver, but the touch shows how tough it is. It sometimes floats in water. There is no everted edge, and on section no acini are to be made out, but the cut surface is indistinct, pale, and yellow. The surface of the liver is smooth.

Under the microscope, using a low power, the tissue of the cirrhotic liver is seen to be broken up into islets, separated by broad bands of what looks like a highly nucleated connective-tissue. The separation between the two appears sharply defined. In some cases the liver-cells may be seen infiltrated with fat. With higher powers, the most striking object in the field is the great abundance of what were once called nuclei, but now lymphatic corpuscles, in the new-formed connective-tissue: these vary little in size or shape, being nearly all round or roundish. The prevailing opinion now is that they are emigrated leucocytes. They are arranged sometimes in clusters, sometimes in lines, and sometimes indefinitely. The origin of the clusters is uncertain; but it seems tolerably clear that the linear disposition arises from the obliteration of vessels carrying bile or blood. The connective-tissue itself is highly fibrous; sometimes homogeneous or granular. The liver-cells themselves undergo great changes. They lose their natural polyhedral shape, and become oblong, oval, or spindle-shaped. Between them the new connective-tissue gradually insinuates itself, and the cells become lost in the advancing overgrowth. These changes in the liver-cells are of course best seen at the spot where the liver-tissue and the connective-tissue join.

SYMPTOMS.—The first approaches of cirrhosis are commonly very insidious. Often one of the first symptoms is a dull pain in the neighbourhood of the liver. This is accompanied by signs of a chronic gastric catarrh, of which morning sickness is, for the diagnosis of intemperance, of the greatest importance. The patients are commonly of a sallow, often almost jaundiced, complexion. They grow thinner, and their strength fails. Some patients suffer from piles: in others diarrhoea occurs. Later on the belly begins to swell, and ascites appears, the legs may become oedematous, from the pressure of the fluid in the belly on the anterior wall of the inferior vena cava. The urine is high-coloured, often deposits urates; and sometimes contains albumin from contracted kidneys.

An important point in the diagnosis is to determine whether the liver is of small size, and growing smaller. This is often difficult, on account of the ascites; the difficulty may sometimes be overcome by laying the patient on his left side. In the earlier stages the hard edge of the liver may at times be felt, and even though the ascites be great, by suddenly depressing the walls of the belly with the fingers. The percussion-dulness of the liver in the nipple line may be reduced to two inches or even one inch in height.

Although in the new-formed connective-tissue of cirrhosis fresh vessels form to take the place of those obliterated, yet these by no means suffice to carry on the circulation through the liver. Portal obstruction therefore arises, which relieves itself in various ways; most commonly fluid is poured out into the cavity of the peritoneum,

causing an ascites, or into the cavity of the intestines, causing a diarrhoea, which should not be lightly checked. In other cases it is relieved by hæmatemesis, or by hæmorrhoidal discharge. That which is most fortunate for the patient is the formation of a varicose communication between some radicles of the portal system and the general veins, as between the hæmorrhoidal and the hypogastric, the veins of the stomach and the œsophageal. Most important of all, however, is a vein discovered by Sappey. It arises from the left branch of the portal vein, and passes up the falciform ligament close to the ligamentum teres to join the epigastric and internal mammary veins. It is by no means the same as the old obliterated umbilical vein, although so near to it. The vein just mentioned will often be found dilated after death.

As a rule the spleen is enlarged in cirrhosis. The enlargement may be very great, but the organ is commonly about twice or three times the natural size. After death the spleen is found of softer consistence than natural, sometimes pulpy. The cause is obscure; the reason commonly given is the hindrance to the flow of blood through the liver acting on the splenic vein. The spleen, however, does not always swell when there is obstruction to the portal circulation, for example, in nutmeg-liver.

Ascites is a symptom which sooner or later is sure to come on. It appears to arise from the viscous stasis in the subperitoneal tissues. Fluctuation, and the movement of the fluid on change of posture are very clear. The fluid, like all other dropsical effusions contains albumin, salts, sometimes urea, sometimes sugar; and in jaundice bile-pigment. After the ascites has set in, the feet may begin to swell, from the pressure of the fluid on the vena cava. The upper limbs and face are free from œdema. In some cases albumin is present in the urine, from coincident Bright's disease.

The patients often complain greatly of flatulence, which adds much to their distress, and dyspnoea. Hæmatemesis and piles are of frequent occurrence. Diarrhoea when it comes in, as above mentioned, salutary, and should not be checked unless extreme. The urine is scanty and high-coloured; often turbid from urates; and bile-pigment is present when jaundice sets in. Jaundice may or may not be seen, according as the pressure of the new connective-tissue does or does not involve the bile-ducts.

DIAGNOSIS.—The diagnosis depends upon the history of intemperance; the size and consistence of the liver; the size of the spleen; and the appearance of ascites and other dropsies. Of importance also is the peculiar sallow earthy complexion; and the occurrence of hæmorrhages from the stomach or intestines. The diagnosis is often easy; while at other times it is very hard or well-nigh impossible to make. Cirrhosis may be confounded with portal thrombosis; obliteration of the hepatic duct; nutmeg-liver; syphilitic disease, cancer, or hydatids of the liver; and chronic peritonitis.

PROGNOSIS.—It is rare for a patient suffering from cirrhosis of the liver to live longer than a twelvemonth after the symptoms have become so pronounced as to allow a diagnosis to be made.

Death is in nearly all cases the end of the disease.

TREATMENT.—In the early stages of cirrhosis it is most important to induce the patient to give up his habits of intemperance, for without this, treatment will be of little avail. Next the use of alkaline purgatives, with or without vegetable matters, such as chiretta or calumina, will be very useful. A course of the waters of Carlsbad is often most useful, or other alkaline or sulphated waters. The diet must be mild, and exercise on horseback or on foot should be recommended.

In the later stages of the disease the great object will be to keep up the strength of the patient. For the ascites, which often becomes the patient's great trouble, diuretics, especially copala, and mercurial alteratives may be employed. Paracentesis should be put off as long as possible, as the end of the disease often arrives soon after the tapping, though in some cases the ascites is cured by this operation. The flatulence should be combated by regulation of diet, charcoal, small doses of hydrochloric acid, and carminatives. The bowels must be kept open, but not severely acted on.

J. WICKHAM LING.

LIVER, Congestion of. See LIVER, Hypertrophia of.

LIVER, Contraction of.—A small liver is met with in cirrhosis, in nutmeg-liver, and in long-continued obstruction to the gall-ducts, in all of which an over-growth of the connective-tissues of the capsule of Glisson is seen. Any kind of pressure on the liver from neighbouring organs will likewise beget wasting. A small liver is seen in old age, and in the marasmus of wasting diseases. The liver likewise wastes if the portal vein be obstructed, or the capillaries in the liver be obstructed, as in pigmented liver. A shrunken liver cannot be looked upon as a disease by itself.

J. WICKHAM LING.

LIVER, Enlargements of.—**ANATOMICAL RELATIONS.**—In proceeding to determine whether the liver is enlarged or not, the following points must be remembered. Normally, the dull sound yielded by percussion extends upwards in front, in a line drawn towards the nipple, to about the sixth rib; laterally, in the axillary region, to the eighth rib; and by the side of the spine, to the eleventh rib. The lower border of the liver corresponds in front and at the side to the lower border of the ribs; and the dulness behind merges into that caused by the right kidney. The left lobe of the liver extends across the epigastrium to the left of the mesial line; the dull sound caused by its upper border merging in that produced by the heart. The upper part of the cavity of the liver rises to a little more than an inch above the sixth rib, the lung dipping down in front; and giving rise to a modified percussion sound; but for practical clinical investigation it is better to take the line of absolute dulness. The extent of the dull sound from above downwards in the right mammary line is nearly four inches, and at the side about four inches and a half. In the middle line in front it extends from the base of the costiform cartilage

to about two fingers' breadth below its point. It should be remembered that the limits of the liver present, compatibly with health, considerable variation; that the organ is relatively larger in early than in adult life; that it is depressed in inspiration, and ascends in expiration; that it is somewhat lower down in the erect than in the recumbent position; and that there is temporary distension during digestion.

DIAGNOSIS.—There are various sources of fallacy which may lead to an erroneous conclusion as to the size of the organ. Thus, an intestine distended with flatus may get in front of the anterior border of the organ, and lead to the supposition that there is contraction, when the contrary is the case. When there is ascites to any extent, it is difficult to make out the boundaries of the liver. In this case however, by placing the patient on the left side, so as to let the fluid gravitate in this direction, a diagnosis may often be effected, also, by suddenly pressing the finger down below the ribs, and thus displacing the fluid, one may sometimes detect the enlarged organ. A rigid right rectus muscle is liable to be taken for a tumour; to obviate this source of fallacy, the patient should lie on his back with his thighs drawn up, and his attention should be diverted by conversation whilst the examination is being made. Sources of fallacy may exist in the liver itself, as in malformations or malpositions of the organ; or they may be outside it, either in the abdomen or chest. Malignant disease of the stomach, omentum, or pancreas; a kidney greatly enlarged by cancerous deposit, or fecal accumulations in the colon, may be mistaken for hepatic enlargement. The following considerations will assist in arriving at a correct diagnosis:—(a) enlargements of the liver, however much they may extend beyond, generally occupy the normal site of the organ, and however irregular the surface, the usual outline may be traced; (b) such enlargements usually follow the movements of the diaphragm in full respiration. Effusion into the right pleura may be mistaken for enlarged liver, especially as this organ may be depressed by it, and so appear to extend beyond its limits in the downward as well as in the upward direction. In pleuritic effusion, however, the dulness on percussion will vary with the position of the patient, and the upper line of dulness will in effusion be straight, in hepatic enlargement convex. Pleuritic effusion and hepatic enlargement may, however, co-exist. Pneumothorax, emphysema of the right lung, thoracic tumours, and even extreme pericardial effusion, may depress the liver, and affect the diagnosis.

ENUMERATION.—Dr. Bright arranged enlargements of liver under two heads, according to the surface of the organ, namely, smooth and irregular. Dr. Murchison considered this classification open to the objection that an enlargement usually smooth is at times irregular, and *vice versa*, and he proposed the division into painless and painful enlargements; but to this similar objection may be taken. The principal enlargements of the liver are associated with the following diseases of the organ.

I. Hypertrophia or Congestion.—The enlargement is not usually, particularly in acute cases, very great; but in chronic cases, and in conges-

tion from obstruction to the circulation, it is often considerable, the organ extending downwards nearly to the umbilicus, and across into the left hypochondrium. The normal contour of the liver is preserved; the surface is smooth; and the resistance is increased. Pain and tenderness are often present, especially in acute congestion.

2. *Obstruction of the bile-ducts.*—Obstruction of the bile-ducts, whether temporary from inflammation or impaction of gall-stones, or permanent, will be attended with some enlargement, smooth and normal in shape, of the liver; with, perhaps, also, distension of the gall-bladder, causing a pyriform tumour, which projects downwards from the anterior border of the liver, and in some cases, of considerable size.

3. *Abscess.*—The presence of numerous pyemic abscesses in the liver will give rise to an enlargement of the organ, with tenderness on pressure over the right hypochondrium. Tropical abscess, when deep-seated, may give rise to like results; but when large and near the surface will, if under the ribs, cause prominence of the right hypochondrium, with obliteration of the intercostal spaces; or when pointing below or to the left of the ribs, will present an elastic, fluctuating tumour, with, perhaps, redness of surface.

4. *Hydatid disease.*—Hydatid of the liver is marked by nearly the same physical signs as abscess, a large hydatid cyst causing according to its site, either bulging of the right hypochondrium, or an elastic tumour either below or to the left of the right lower ribs. The tumour in some cases gives a sense of fluctuation, and the peculiar vibratory tremor known as hydatid-fremitus. A hydatid cyst may attain much greater magnitude than is ever reached by abscess, and may occupy the greater part of the abdomen. Unlike abscess, hydatid disease, unless the cyst is suppurating, is unattended by pain or constitutional disturbance.

5. *Simple hypertrophy.*—Simple hypertrophy of the liver, resulting from an increase of the size or number of the secreting cells, causes a painless enlargement, having the normal shape of the organ, but attaining at times to twice its normal size.

6. *Fatty degeneration.*—This morbid condition of the liver causes a painless enlargement, not usually very great; with preservation of the normal outline and smooth surface of liver, but with diminished resistance.

7. *Albuminoid degeneration.*—In albuminoid disease the liver preserves its shape, is large; usually has a quite smooth surface; and is hard and resistant to the touch. Enlargement from this cause is sometimes very great, and second only to that which results from malignant disease. The surface in albuminoid disease is sometimes irregular, from co-existence of cirrhosis or syphilitic cicatrices. The spleen is usually enlarged.

8. *Malignant disease.*—In malignant disease the liver is not always enlarged; and in the infiltrated form, the surface may be smooth. Usually, however, especially when the disease is advanced, there is enlargement, with loss of normal shape; and the surface is hard and resistant, and covered with nodules, or large knobs

and protuberances. The greatest enlargement—sometimes such as to occupy the greater part of the abdominal cavity, is attained in this disease. Pain, varying in character and intensity, seated in the liver or distal, is also generally present.

9. *Cirrhosis.*—In some cases of cirrhosis the liver may be found enlarged, as in the so-called 'hypertrophic' form. See LIVER, Cirrhosis of. STEPHEN H. WARD.

LIVER, Fatty Disease of.—DEFINITION. A disease attended with painless enlargement and diminished consistence of the liver, due to the presence of a large quantity of fat or oil in the secreting structure; and occurring in connection with phthisis and other wasting diseases, or in persons of luxurious and indolent habits, in whom there is usually an abundant development of fat in the tissues and other organs.

ÆTIOLOGY.—Fatty liver may either be due to degeneration of cell-structure through faulty nutrition, or it may result from infiltration of the cells with fat, transmitted through the portal vessels from without (fatty infiltration.) Fatty degeneration is met with in association with other hepatic diseases, as albuminoid disease and cancer. The fatty liver which results from poisoning by phosphorus would, according to the experiments of Voit and Rufer, appear to be due to degeneration, as the dogs upon which they experimented had been kept without food previously, and were starved during the time phosphorus was administered; showing that the fat could not have come from other parts of the body, or been introduced in food, but must have resulted from the metamorphosis of tissue-material. It is with fatty infiltration that we are more particularly concerned. The fat may come either from within or from without the body. The former case is illustrated when the greater part of the fat of the tissues and organs is absorbed, as in the emaciation of advanced phthisis. Louis, who first established the association of fatty liver with phthisis, found it to exist in about one-third of the cases of this disease, and met with it much more frequently in phthisical females than in males. His observations have been amply confirmed by subsequent observers. Fatty infiltration of the liver also occurs in connection with other wasting diseases, and is not infrequent in patients who have been long bed-ridden. From a therapeutical point of view, the medical practitioner is more interested in the disease under consideration, when fat is introduced from without the body. The affection of the liver is then associated with development of fat in other organs and in the tissues generally. Persons thus affected are usually given to undue indulgence in eating and drinking; to eating not only too much food, but food rich in oil and fat, and drinking beer, but especially spirits to excess. Want of exercise of mind and body, a heated atmosphere, and general luxurious habits, materially assist in determining the affection. In illustration of this cause may be adduced the oft-cited experiments of Magendie, who induced very fatty livers in dogs by feeding them exclusively on butter; and also in the production of the *foie gras* in geese, by penning them up in a heated atmosphere and cramming them.

ANATOMICAL CHARACTERS.—In fatty disease the liver is more or less enlarged, but seldom to any great extent; the surface is smooth; the borders are rounded; the substance pits on pressure; and the organ is either of pale yellow or drab colour, or, when partially affected, has a mottled appearance. A portion placed in water floats, showing a diminished specific gravity. On cutting into the organ, the knife is greased, and a greasy stain is imparted to blotting paper applied to the cut surface. A portion when held in the flame of a lamp or candle, will, when the water is driven off, burn. It is, however, as Frerichs remarks, only by the microscope that the degree to which the liver is implicated can be determined. In slighter grades, fat-granules and globules are seen to be limited to the outer zone of the lobules in the vicinity of the portal vessels; but in advanced cases the whole of the cells will be found to be filled either with separate globules, or with a single large drop of fat. In less extensive infiltration the liver may be marked by red spots, corresponding to the hepatic veins. Fat in limited quantity is always present in the human liver, so that the term fatty can only be applied when it is in excess.

SYMPTOMS.—In the lesser grades of the disease, there are scarcely any distinctive symptoms, either objective or subjective. When the affection is more pronounced, percussion will indicate more or less enlargement, usually in the downward direction; and palpation may detect a rounded border and diminished consistence, and will, at any rate, determine that the organ is not unduly hard, has no irregularity of surface, and does not differ materially in shape from the healthy liver. There is seldom, if ever, any pain; at most, in marked cases, a sense of tension and of uneasiness on lying on the left side. Jaundice is a rare event; and ascites and enlargement of the spleen cannot be classed as symptoms of the disease. In cases of fatty infiltration, dependent on luxurious habits, as regards diet, &c., there is usually more or less development of fat in other organs, as well as in the omentum and subcutaneous cellular tissue. There is also a greasy condition of skin, with peculiar odour, resulting from abnormal oily secretion from the sebaceous follicles. Dr. Addison considered a peculiar condition of the skin—preventing to the eye a bloodless, almost semi-transparent, and waxy appearance, and to the touch a feeling of smoothness, looseness, and flabbiness—as indicative, if not pathognomonic, of fatty degeneration of the liver. In cases where the liver is much enlarged, and there is much abdominal fat, the upward pressure may interfere with the action of the diaphragm, and cause, especially after meals, embarrassment of breathing. The functional symptoms likely to be present in advanced cases are irregularity, generally sluggishness, of the bowels; more or less dyspepsia; and, perhaps, loss of appetite. In some cases a weak or irregular, or intermittent action of the heart, with tendency to faintness or giddiness, points to implication of this organ, and is indicative of possible fatal consequences.

DIAGNOSIS.—The enlargement of the liver, with preservation of its normal shape, without hard-

ness or irregularity; the absence of pain, jaundice, ascites, or enlargement of the spleen; and its association either with the emaciation of phthisis or other wasting diseases, or with the habits of the gourmand and general development of fat in the body, will usually enable us to distinguish fatty from other hepatic enlargements.

PROGNOSIS.—The prognosis of fatty disease of the liver is affected by the associated general condition of the patient, and will, of course, be unfavourable in phthisis.

TREATMENT.—The general therapeutical indications in fatty liver resulting from luxurious habits of living, point to reform in the direction of diet, air, exercise, &c. Rich, oily, and fatty articles of food are to be avoided; whilst sugar and starch should be taken in moderation. Beer, in all forms, is objectionable, and so also is alcohol, unless well-diluted, and taken only at meals. Champagne is objectionable, but other light French wines are admissible. Exercise, either on foot or horseback, should be had recourse to daily, but must be regulated according to the soundness of the heart and circulation. Free exposure to pure air, and avoidance of heated rooms, are desirable. The functions of the skin must be promoted by adequate clothing, and by the use of the bath, or by sponging with soap and warm water. The bowels must be attended to, and dyspepsia met by antacids and vegetable bitters. The Carlsbad waters—the warm Sprudel especially—are indicated, being supposed to act upon the redundant fat.

STEPHEN H. WARD.

LIVER, Functional Disorders of.—INTRODUCTORY REMARKS.—The late Dr. Copland, in his *Dictionary of Practical Medicine*, arranged these disorders under three heads, according to the nature of the biliary secretion. 1. Diminished secretion of bile, 2. Excessive secretion of bile, and 3. Vitiated biliary secretion. Dr. Budd, whilst recognising the functions of the liver as threefold, namely, as to changes effected in the blood, the formation of sugar, and the secretion of bile, almost restricts what he says upon the subject of functional disorders to abnormal conditions of the secretion—excessive, defective, or unhealthy bile. The late Dr. Murchison, in his lectures on *Functional Derangements of the Liver*, showed that the classification heretofore adopted, does not represent the present state of knowledge of the functions of the organ. He summarises these functions under three heads:—

1. The formation of glycogen, which contributes to the maintenance of animal heat, and to the nutrition of the blood and tissues.
2. The destructive metamorphosis of albuminoid matter, and the formation of urea and other nitrogenous products, which are subsequently eliminated by the kidneys; these changes also maintaining the animal heat.
3. The secretion of bile, a large portion of which is reabsorbed, assisting in the assimilation of fat, and other elements; whilst a part, passing downwards, stimulates the peristaltic action of the intestines, and arrests decomposition. The author just cited arranged the phenomena of functional derangements of the liver under nine heads. 1. Abnormal nutrition. 2. Abnormal elimination.

3. Abnormal disintegration. 4. Derangements of the organs of digestion. 5. Derangements of the nervous system. 6. Derangements of the organs of circulation. 7. Derangements of the organs of respiration. 8. Derangements of the urinary organs. 9. Abnormal conditions of the skin. The above heads, however, represent for the most part functional and general symptoms resulting from functional hepatic disorders, rather than these disorders themselves. The arrangement under three heads, representing the three principal functions of the organ, is that which the writer proposes to adopt.

Ætiology.—It is scarcely necessary to remark that functional disorders of the liver are often secondary to structural diseases of the organ, or to diseases of the thoracic and abdominal viscera, febrile affections, malaria, and other causes. It is with the causes which induce these disorders when primary, that we are here concerned. Prominent among such causes are errors in diet, and the undue use of alcoholic liquors. Habitual over-eating, and especially indulgence in rich, fatty articles of food, such as rich soups, entrées, and pastry; and the undue use of sugar, fish or flesh containing much oily matter, are very apt to disturb the function of the liver. Excess in the use of alcoholic drinks is another cause, in this country, in frequent operation. The combination of sugar with alcohol much enhances the mischief. Hot, sweetened grog, sweet new wines, as champagne, unless dry, Madeira and sweet sherris; port-wine, liqueurs; and malt liquors, particularly mild ales and stout, are ready causes of hepatic derangement. Want of exercise, whether the result of necessity or of indolent habits, is another common exciting cause of hepatic functional disorders; and its effect is enhanced when it is associated with errors in diet. Living habitually in a high temperature, whether in a warm climate or in over-heated rooms, is another cause, and is intensified when associated with the causes already alluded to. Depressing nervous and emotional influences must not be forgotten in considering the ætiology of the subject.

Symptoms.—The phenomena which are observed in functional derangements of the liver may now be briefly indicated, according to the particular hepatic function which is disordered.

1. Disorders of the Glycogenic Function.—Disorders relating to the glycogenic function fall under the subject of diabetes, and need here only be alluded to. See DIABETES.

2. Disorders of the Metabolic Function. In reference to derangements from faulty function connected with albuminoid disintegration, &c., the writer quite concurs with, and will concisely state the views advanced by Dr. Murchison. One of the immediate results of such faulty function is the non-conversion of nitrogenous matters into urea, and the production of lithates and lithic acid, inducing a condition of blood to which this authority fitly applied the term *lithæmia*. This lithæmia may be relieved for a time by elimination by the kidneys, showing itself in deposits in the urine, on cooling, of lithic acid, lithates, and pigmentary matter. These deposits are not unfrequent in persons in good

health, especially after any excess or error in diet; and they are more or less constant in subjects of gouty habit of body, and in those who are predisposed to hepatic derangement, or who induce it by habitual over-stimulating diet. These deposits may exist for years without causing much discomfort; but after a time, the excessive quantity of lithic acid and lithates cannot be eliminated by the kidneys; and they accumulate, causing disturbances in different parts of the organism, and giving rise to various more or less distressing symptoms. Of these symptoms the more prominent are:—epigastric oppression, flatulent distension of stomach and bowels, heartburn, acid eructations, sense of weariness and tendency to sleep after meals, furred tongue, unpleasant taste in the mouth, especially in the morning, appetite often good, sometimes the contrary, an excessive secretion of viscid mucus in the fauces and back of the nose, constipation and vitiated secretions. Palpitation, irregular or intermitting pulse, frontal headache, vertigo, noises in the ears, redness at night, irritability of temper, and hypochondriasis, are other symptoms that are not unfrequently present.

Gout, whether openly expressed, latent, or irregular, is associated with the symptoms just mentioned, and is one of the results of lithæmia, and of faulty hepatic function.

Urinary calculi are another result of lithæmia, at all events, those which consist of lithic acid or its salts, and which are the most frequent. Sir H. Thompson confirms this view, and shows that the formation of these calculi is to be prevented by remedies and a *regime* directed to the liver rather than to the kidneys.

Biliary calculi are also a result of functional hepatic derangement, and are frequently associated with a gouty habit of body, and with lithic acid deposits and calculi.

Lithæmia predisposes to local inflammations. Individuals who are subject to deposits of lithic acid and lithates are more liable than others to severe local inflammations, and in reference to this fact, Dr. Murchison made the practical observation that in such persons the lithates cease to be eliminated on the advent of a local inflammation or ordinary febrile catarrh, to be again discharged freely on the subsidence of the pyrexia. In such cases, he added, the retention of lithates in the system has probably determined the attack.

Some diseases of the skin, as eczema, psoriasis, lichen, and urticaria, are unquestionably often induced and maintained by lithæmia and the hepatic derangement from which it results.

To conclude this portion of the subject, the functional derangement under consideration, as Dr. Murchison remarked, 'by the production of peccant substances which are not readily eliminated, and which, therefore, accumulate in the system, may in the long run lead to many of the most serious maladies, both acute and chronic, to which our race is subject.'

3. Disorders of the Biliary Function.—Disorders referable to faulty biliary secretion may be divided into (a) those due to excessive secretion; and (b) those due to deficient secretion. It is scarcely necessary to arrange these due to vitiated bile under a separate head, as the secre-

tion may be vitiated, whether it be redundant or deficient.

(a) *Excessive secretion of bile* is characterised by bilious diarrhoea—copious, fluid, bilious evacuations, nausea, or not unfrequently vomiting; twisting, griping pains in the abdomen; and perhaps some febrile symptoms. The bile in some cases seems to be peculiarly acrid, and causes much smarting when it is voided. The urine is generally high-coloured, and loaded with lithates. There is frequently headache, and either irritability of temper or depression of spirits. Disturbances of circulation, in the form of irregularity of pulse, and palpitation of the heart, are also occasionally present. As has been stated under the article *LIVER*, Hyperæmia of, this excessive secretion of bile, with the attendant symptoms, is usually the result of congestion of the liver.

(b) *Deficient secretion of bile* is characterised by dyspeptic symptoms, such as furred tongue, unpleasant taste in the mouth, loss of appetite, and flatulencia. The action of the bowels may be irregular, but is usually costive, and the evacuations are of a pale yellow, or drab, or whitish colour, and often of offensive odour. The complexion is usually sallow and anæmic, not often jaundiced. Disturbances of the circulation, in the form of languid or irregular pulse, and of the nervous system, as headache, languor, drowsiness, and hypochondriasis, are frequent concomitants. The urine is generally dark-coloured, turbid, and loaded with lithates. There is also, in cases of long standing, loss of flesh. Indeed, the functions of the bile in promoting the assimilation of fat, in stimulating the peristaltic action of the intestines, and as an antiseptic, are well illustrated in the symptoms which attend protracted deficiency of the secretion.

TREATMENT.—Among the remedies which promote the expulsion, if not the secretion of bile, mercury and its preparations hold a prominent place. For notwithstanding the results of experiments upon animals, few practitioners will be content to give up the advantage which their clinical experience has taught them is to be derived from the judicious use of mercury. It is possible that the drug merely effects the expulsion of the bile; the result, however, is unquestionable. In excessive secretion of bile a single full dose of calomel, followed in a few hours by a saline draught, will cause a free downward discharge; and in the lithæmic condition of system, indicated by turbid urine containing copious lithates, the same treatment will afford ready relief. In smaller doses, repeated at intervals, and combined with other aperients, as colocynth, or rhubarb, mercury will be followed by beneficial results in less active functional derangement. In some cases mercury is inadmissible, or disagreeable, and, in any case, it is well not to repeat it too frequently, or to continue it for too long a time, as its protracted use is apt to impair digestion and nutrition, and weaken the function of the organ which it at first cures. Of late years a valuable addition to the list of cathartics has been made in podophyllin. A quantity of a grain to a grain of the resin may be given for a dose, combined with a little sugar, or as half a grain of extract of canna-

bis indica to prevent griping, and a grain or two of rhubarb or watery extract of aloes, or, if it is desirable to quicken the action, with some extract of colocynth, or it may be given in solution as a tincture. When the drug acts favourably it produces one or two bulky evacuations, with copious excretion of bile, followed by a feeling on the part of the patient that the bowels have been thoroughly emptied. Its action, however, is at times neither satisfactory nor certain, and it causes occasionally much griping, irritation, and tenesmus, and subsequent depression. Taraxacum is useful as an aperient, and probably alterative, in functional hepatic disorders, and may be given in cases where the gouty or lithic acid diathesis exists, in combination with alkalies, especially the bicarbonate of potash. The fresh extract, in ten to fifteen-grain doses, acts better than the juice. Nitro-muriatic acid is indicated in cases of torpid liver associated with oxaluria (see *LIVER*, Hyperæmia of). The saline aperient draught has of late been in a great degree superseded by one or other of the aperient mineral waters, the Friedrichshall, Pullna, Hunyadi, &c. These should be taken in the morning, fasting, and their effect is quickened by the addition of some warm water. The action of these waters, as of the saline purgative, is to cause a drain from the intestinal vessels, and thus to relieve the congested hepatic portal system. The waters of Carlsbad, Marienbad, and other similar springs contain no sulphate of magnesium, and owe their aperient effect to the sulphate of soda which is the preponderating ingredient. This drug does not act by stimulating intestinal secretion, but, according to Buckheim, by retaining the water in which it is dissolved and that which it meets with in the bowel, and so constituting a solvent which loosens and softens and carries down dried fecal masses, and tenacious mucus. The amount of carbonate of soda associated with the Glauber's salt in these waters renders them antacid, and assists in determining a diuretic as well as aperient action. The mineral waters, or the salts obtained from them by evaporation, may be taken at home in the morning, in conjunction with sufficient warm water. For those individuals especially who are suffering from hepatic congestion or merely functional disorder, especially if the result of irregular habits in eating and drinking, a visit to and course of waters at one of the spas will, if means permit, be desirable. Change of scene, regularity in diet, and absence from mental harass, are, of course, important elements in the success of a more or less protracted stay at such places; and it is remarkable how readily many individuals, who are quite unmanageable at home, submit to strict hygienic arrangements under fresh influences. Cheltenham, Leamington, and Scarborough in this country, and in addition to those already named, Homburg and Kissingen on the Continent, are amongst the spas which enjoy special renown in the treatment of liver-affections. See *MINERAL WATERS*.

In no class of disorders do general remedial or hygienic agents act more beneficially than in functional derangements of the liver. Pure air

exercise, strict attention to the functions of the skin, and suitable diet, are the curative means on which we must mainly rely. In all cases it is of moment to promote the healthy action of the skin and lungs. This is to be done by exercise on foot or horseback. The latter is peculiarly advantageous, as it stimulates directly, by a series of spasmodic, and by contraction of the abdominal muscles, the liver and intestines, and may be had recourse to, in moderation, by those who are not very vigorous. Walking promotes the general circulation, excites the action of the skin, increases the frequency and fulness of the respirations, and indirectly tends materially to relieve a congested or indolent state of liver. The action of the skin must also be maintained by adequate clothing in all seasons of the year, and by daily use of the sponge-bath, followed by active friction of the entire surface of the body.

The diet should be of a light nourishing character, and rich gravies, made dishes, soups, sauces, pastry, raw vegetables, and such articles, should be carefully avoided. The nitrogenous foods suit best, especially where there is associated lithæmia; starchy and saccharine articles being objectionable. The stronger spirituous drinks are to be entirely avoided, but the lighter wines, as claret, hock, and light dry sherry, may be taken at meals in moderation.

LIVER, Gangrene of. See **LIVER, Abscess of**, and **Inflammation, Acute, of**.

LIVER, Hydatid Disease of.—**SYNON.**: Echinococci of Liver.

ANATOMICAL CHARACTER.—The liver is the organ most frequently affected with hydatid disease. There is usually but one cyst, but there may be two, three, or more; and the size of the cyst may vary from that of a pea to that of a child's head. The cysts may exist in either lobe of the liver, but they are more frequent in the right, and they may be attached to the upper or under surface, or project from the border, or lie buried in the substance of the gland. This is more or less modified in form, and increased in size, according to the magnitude and site of the cyst. When the cyst is small and deep-seated, there will be no appreciable change in the liver, and the disease may be latent for years. When, however, the cyst is very large, it, with the liver, may constitute a tumour, which may encroach upon the thorax, and also fill a great part of the abdomen. Pressure of the cyst may induce atrophy of a portion of the liver, but, at times, hypertrophy is the result. The bile-ducts have occasionally been found to be obliterated, or a communication to have been effected between them and the cysts. When at the surface of the organ, the cysts as they enlarge may induce inflammation and thickening of the peritoneum, and adhesion to neighbouring structures.

SYMPTOMS.—A hydatid cyst, when sufficiently large and near the surface, generally exhibits itself as a tumour of variable size, situated either in the right hypochondrium or in the epigastric region; evenly globular in its early stages; firm, resisting, yet elastic, and, at times, with a sensation of fluctuation. Brienceau and Piorry

noticed a vibration or trembling—hydatid fremitus—which is felt when the surface is compressed gently by three fingers of the left hand, and sharp percussion made with the right hand over the middle finger. Frerichs does not consider this sign of much importance, it having been present in only one-half of his cases. If the tumour is situated behind the liver, it will, as it develops, push this organ forwards, flatten it, and increase the area of dullness. The tumour may last for a considerable time, and go on increasing to some extent, and yet the patient remain free from constitutional disturbance, perform all his functions well, and keep in good condition as regards flesh and strength. When, however, it has attained a very large size, it will give rise to various symptoms, to a feeling of tightness and distension; if it press upwards, to embarrassed breathing, cough, and palpitation; if upon the abdominal viscera, to interference with their functions. Pain is not generally present, but in some cases there is a gnawing pain, either at the epigastrium, or extending forwards from the lumbar region. Œdema of the lower extremities may occur when the tumour presses upon the inferior vena.

DIAGNOSIS.—Hydatid tumour of the liver is not always easily diagnosed, but the characteristic features already noticed, and its compatibility (in many cases up to an advanced stage) with a good state of health, will generally point to its nature. Abscess of the liver will be distinguished by local and remote pain; the frequent antecedence or co-existence of dysentery; and severe constitutional symptoms, such as hectic fever, rigors, &c. It must, however, be remembered that hydatid cysts are liable to become inflamed and to suppurate, when the diagnosis will not be so readily made. Cancer of the liver will generally be marked by irregularity of surface, the presence of pain, the cachectic aspect; and the rapidity of progress. Aneurism of the abdominal aorta may form an epigastric tumour, of even, spherical shape, but the pulsations, frequently very forcible, coupled, probably, with bruit, audible along the course of the vessel before and behind, will determine the diagnosis. The site, the pyriform shape and uniform size, and the usual accompaniment of jaundice, will distinguish from hydatid disease the tumour caused by a distended gall-bladder. Frerichs thinks that hydatid disease of the liver is more frequently confounded with localized pleuritic effusion at the base of the chest than with any other affection. He remarks that the same signs—dullness on percussion, absence of vocal thrill, intercostal fluctuation—would be present in both cases. He rests the diagnosis on the fact that the line of dullness would present a curve which would look upwards in the one case, downwards in the other.

PROGNOSIS AND TERMINATIONS.—Hydatid tumour of the liver may last for years, and be compatible with an average state of health; or at an early or advanced period of its existence, it may terminate in one of the following ways:—
1. It may, from its bulk and position, press upon and interfere with the functions of different organs. Pressure on the large venous trunks may induce ascites and dropsy of the lower ex-

tremities; pressure upon the stomach and intestinal canal may obstruct functions connected with the assimilation of food, and induces failure of flesh and strength, and ultimately death from exhaustion. 2. The tumour may contract adhesions with the diaphragm; ulcerative action through this may be set up, and either (a) discharge of the contents of the sac may take place into the pleura, and fatal pleuritis result, or (b) further adhesions and ulceration may effect communication with the lung, pneumonic symptoms ensue, and the contents of the sac, mixed with the products of inflammation, be expectorated. 3. A rare result is adhesion to, and ulceration into the pericardium, with escape of contents, and rapidly fatal results. 4. Adhesion may be effected with some part of the alimentary canal, and the contents of the sac be discharged by vomiting or by stool. 5. Rupture of the sac may be caused by a blow or otherwise, the contents be discharged into the peritoneum, and fatal peritonitis result. 6. The tumour may contract adhesions with the parietes, point externally; and be opened or effect an opening by natural process, inflammation and suppuration having been previously set up in the sac. 7. Badd and Frerichs notice a possible cure from the obliteration of the sac by the formation within it of a putty-like matter, which involves or perhaps results from destruction of the cysts. 8. Communication may be effected between a cyst and one of the bile-ducts and then the result will usually be fatal, although there are one or two cases recorded of recovery. 9. Similar cysts may be formed in other parts or organs of the body. 10. As a possible rare event may be mentioned communication of the sac with the ascending vena cava, escape of the contents into this, transfer of the contents to the right side of the heart, impaction in the pulmonary artery, and fatal asphyxia.

TREATMENT.—So long as a hydatid tumour induces no distressing symptoms, and does not affect the functions of any organs, there is no pressing cause for interference. When, however, it is rapidly increasing, is accompanied with pain or distressing distension, and especially if by upward pressure it is causing difficulty of breathing, and other symptoms, it will be well to have recourse to tapping. If there be any doubt about the nature of the tumour, the exploratory needle may be first introduced, and should a clear fluid, free from albumen, escape, the case may be fairly pronounced to be one of hydatid disease. It is now, indeed, considered the best treatment not to wait for urgent symptoms; but when the disease is well developed, the cyst yet perhaps single, and the walls elastic, to let out the contents. This is best and most safely effected by puncturing with a fine trocar or with an aspirator. Certain precautionary measures must, however, be attended to. Prior to tapping, a broad flannel roller should be firmly applied round the abdomen, commencing from below and carrying the bandage up to the tumour, so as to assist in fixing this. It is considered desirable not to quite empty the cyst, as by doing so the chance of air entering the cyst is increased. This result may also be further prevented, and adhesion of the cyst to the

parietes promoted, by applying a compress of lint over the wound and fixing it firmly with the remainder of the bandage which has been already partially applied. The patient should be kept quiet in bed for a day or two, and rest should be further ensured by the administration of morphia. The late Dr. Murchison disapproved the use of chloroform for this operation, as the pain is but trifling, and the chloroform may induce vomiting, which would interfere with the subsequent rest of parts, so desirable to ensure a successful result. It is not necessary to wait for the adhesion of the cyst to the parietes before puncturing, as the use of a fine trocar diminishes the risk of escape of the contents of the sac into the peritoneum; and, moreover, the escape of a certain amount of fluid will not usually induce peritonitis. A large proportion of cases thus treated have been successful. When a hydatid cyst has suppurated, it should be opened with a large trocar or a bistoury, and kept open. Puncture and subsequent injection of the cyst with some stimulating fluid, gradual opening of the cyst by applications of caustic potash, so as to ensure adhesion with the parietes, and a large incision with a view to effect the removal of contents, are methods of treatment which have been practised, but cannot be recommended in comparison with simple puncture with a fine trocar. Dr. Hilton Fagge and Mr. Durham treated several cases successfully by acupuncture, and by passing a galvanic current through the contents of the cyst, but it seemed probable that the result was due to the acupuncture, and not to the galvanic influence. Treatment by special medicinal agents, administered internally, has been fairly tried. Of these, common salt and iodide of potassium in large doses may be mentioned. They have, however, proved useless. **STEPHEN H. WARD.**

LIVER, Hyperæmia of.—SYNON.: Congestion of the Liver.

DEFINITION.—Uniform enlargement of the liver, with preservation of its normal shape, caused by over-distension with blood, the result of mechanical obstruction to the return of blood to the heart, or of direct afflux of blood through the portal vessels; attended with a sense of fullness and oppression in the right hypochondrium and in the epigastric region, a dusky and sometimes jaundiced complexion, and terminating, if not relieved, in organic changes in the hepatic parenchyma.

ÆTIOLOGY.—Congestion of the liver may be either *active* or *passive*. Niemeyer limits the term 'congestion' to the latter, and applies the term 'fluxion' to the former. *Active hyperæmia*, or congestion, results from—1. Excess in eating and drinking, especially in persons of sedentary and indolent habits. Determination of blood to the liver occurs, to some extent, in the process of digestion in connection with ordinary meals, and if these consist of rich and irritating materials, and are repeated too often, or if the liver is stimulated between meals by the imbibition of spirituous liquors, the hyperæmia may become excessive and continuous. 2. Long exposure to a tropical or sub-tropical temperature will, perhaps, induce hepatic congestion, but

such influence may be long resisted by persons of temperate habits, and it is probable that the association of irregularities in eating and drinking mainly contributes to the result. 3. A chill, after exposure to heat, may induce active hepatic congestion, which, in hot climates, may result in suppurative hepatitis. 4. It may be excited by injuries to the liver—such as contusions or wounds. 5. It occurs in connection with suppressed menstruation, especially in women of full habit of body, and who are approaching the period of 'change of life.' 6. Hyperæmia of the liver with enlargement occurs in connection with 'typhus fever, the acute exanthemata, puerperal fever, scurvy, &c.' It is also a result of prolonged exposure to malaria, with or without attacks of pronounced ague. This influence is the main cause of the enlarged livers with which 'old Indians' return to this country. *Passive hyperæmia*, to which the term *mechanical* is applied by some authors, is due to interference with the return of blood from the liver through the hepatic vein and inferior vena to the heart. Such interference may be due immediately to dilatation of the right heart, with affection of the tricuspid valve; to obstruction to the circulation in the course of the pulmonary arteries, caused by different diseases of the lungs, or farther on, in the line of the circulation, to disease of the mitral or aortic valves. The affection of the lungs which interfere with the pulmonary circulation are either acute, as pneumonia, and then the hepatic hyperæmia may pass off with the disease, or they are chronic, as emphysema, and fibroid disease, and then the hyperæmia will persist. Mechanical congestion of the liver may result from direct obstruction to the flow of blood by the pressure on the vena cava of aneurismal or other tumours. Mere weakness of the heart's action often keeps up a certain amount of passive congestion.

ANATOMICAL CHARACTERS.—A hyperæmic liver is increased in size about equally in all directions; its resistance is also increased; its peritoneal investment appears distended and shining. On making an incision blood oozes out freely, and the cut surface is dark red, either uniformly so, or spotted with intervening lighter spaces. In the active form of congestion there is engorgement of the portal vessels at the periphery of the lobules, in the passive or mechanical form, the central vessels of the lobules—the hepatic veins—are engorged. In the latter form, when it is due to a persistent cause, as disease of the mitral valve, and has lasted some time, the cut surface gives the characteristic appearance to which the term *nutmeg-liver* has been applied. The dark centres contrast with the pale circumference of the lobules, the light and dark parts are clearly defined, varying according to the section; the surface gives an appearance which resembles closely that of a cut nutmeg. The central dark spots result from distension of the hepatic veins, and deposition of bile-pigment in the adjacent hepatic cells, which are more or less atrophied by pressure; the lighter spaces correspond to the interlobular veins, the light colour being due, according to most pathologists, to the presence of fat in the cells at the circumference. Dr. Wickham Legg,

however, states, as the result of an examination of twenty cases of nutmeg-liver, that the fat was not in excess in the majority of them. In addition to the atrophy of the cells by pressure of dilated hepatic veins, there is hypertrophy of the interlobular hepatic tissue, with lymphoid bodies scattered through it and, in later stages, through the liver generally, and it is on this latter cause, as in cirrhosis, that the shrinking of the liver in advanced cases depends. The term '*red atrophy*' has been applied to this advanced stage of nutmeg-liver, but, as Dr. Legg remarks, it is objectionable, as having been previously used by Virchow to designate a state of liver met with in wasting diseases, such as typhoid fever. The term '*atrophic nutmeg-liver*' answers well. '*Varicose atrophy*,' used by some writers, is based upon the dilated condition of the central vessels and their radicles.

SYMPTOMS AND SIGNS.—In slight cases of hyperæmia the liver does not extend much beyond its normal limits, but it may perhaps be felt below the borders of the ribs and across the epigastrium. In severe cases and especially in passive hyperæmia from obstructed circulation, the organ often attains a considerable size, and is found, on percussion, to extend upwards into the mammary region, downwards nearly to the umbilicus, and across into the left hypochondrium. Its resistance is generally increased, and, in old-standing cases resulting from malaria and hot climate, it has an amount of hardness which characterises and probably indicates, albuminoid degeneration. There is often, especially in acute cases, tenderness on pressure. The patients do not exactly speak of pain, but of a sense of oppression and fulness in the right hypochondrium and in the epigastric regions, and of uneasiness from the pressure of clothes, or on lying on the left side. In most acute cases there is marked functional and general disturbance, a furred tongue, nausea, vomiting at times of bile, bilious diarrhoea, sallowness of complexion, or some amount of jaundice. In some cases the bile seems to be peculiarly acrid, and causes much griping and distress as it passes downwards, and smarting as it is voided. The urine is high-coloured, and loaded with lithates. The patients often complain of headache, are irritable, depressed in spirits, and feel languid and drowsy. Disturbances of circulation are indicated, in severe attacks, by irregularity of the pulse, and palpitation of the heart. When jaundice, in any marked degree, is present, there is probably catarrh of the bile-ducts, and transient obstruction of these ducts, and then the evacuations are devoid of bile. The hyperæmic condition of liver induced in India or other tropical regions, as the result of high temperature and malarious influence, may terminate in chronic enlargement, and possibly in changed structure of the organ. The symptoms which mark this are cachexia and anæmia, with sallowness of complexion; a weak circulation, indicated by great susceptibility to changes of temperature, by chilliness and coldness of the lower extremities; disturbances of nervous system, shown by irritability, depression of spirits, disinclination for effort of any kind, headache, giddiness; and other symptoms. Dyspeptic symptoms are

present. The bowels are either constipated or relaxed; the stools in either case showing a deficient or vitiated secretion of bile. The urine sometimes contains bile, frequently exalts of *Urea*, and excess of *urea*. The skin is dry and harsh. Individuals with such a condition of liver may prolong their existence for years; or the serious interference with nutrition may induce increasing loss of flesh and strength, and premature death.

In the mechanical form of hyperæmia there are, in addition to special gastric and hepatic symptoms, other symptoms indicative of the pulmonary or cardiac affection on which it depends. The complexion is more or less dusky, and there is a certain amount of lividity mixed with the jaundiced hue. The liver, which may have become much enlarged, will, if observed carefully in any protracted case, often be found again to diminish as the atrophic change takes place. Ascites may now become a prominent symptom, whilst, as Niemeyer remarks, the general dropsy resulting from associated heart-affection may be yielding to treatment.

DIAGNOSIS.—Hyperæmia of the liver, when it is the result of obstruction to the circulation caused by diseases in the chest, is easily recognised. Also, when of the active kind and acute, it is not likely to be mistaken for any other cause of enlargement. It is only when the congestion is chronic, and the liver hard and resistant, that an erroneous diagnosis may be made, but the previous history of the case, and associated general symptoms, will lead to a right conclusion. It might be mistaken for albuminoid disease, but then it may be really undergoing this degeneration.

PROGNOSIS.—Active hyperæmia of the liver usually ends favourably on removal of the exciting cause, and under appropriate treatment. The following considerations will, however, influence the prognosis. 1. An attack of hyperæmia in an individual of intemperate habits may be but the early stage of cirrhosis. 2. A similar attack, occurring in India, may, as Dr. Maclean remarks, be but the commencement of acute hepatitis, which may end in suppuration. 3. The prognosis in the mechanical congestion, dependent upon disease in the chest, will be influenced by the nature and stage of such disease.

TREATMENT.—An attack of acute hyperæmia of the liver will usually be relieved quickly by rest; by restriction to a bland, fluid diet; and by ensuring free action of the bowels by a dose of calomel, followed after a few hours by a saline aperient, either in the form of a draught, or of one of the more active mineral waters. A single sufficient dose of calomel, four or five grains, will often rapidly relieve attendant gastric irritation and vomiting, and ensure a free downward discharge of bile. Should there be much tenderness on pressure over the liver, the application of stupes or turpentine stupes, followed by hot poultices, will be beneficial. So long as any acute symptoms continue, the patient should be kept quiet in bed; the diet should be light and fluid; and stimulants should be rigorously excluded. The portal system must be kept relaxed by a dose of *Salina* or *Friedrichshall* water, or a saline draught, every or every other

morning, preceded the previous night by some mercurial preparation, if the secretion seem to require this. Podophyllin may be advantageously substituted for mercury, in some cases, but it is uncertain in its action. Its gripping effect is counteracted by the addition of a little extract of hyoscyamus or half a grain of extract of cannabis indica, and its action will be quickened by adding a little compound colocynth pill. When the acute stage of hyperæmia is passed, taraxacum often acts well as a purgative and alterative; combined, in subjects of gouty habit, whose urine is more or less charged with lithates, with bicarbonate of potash, or in other cases, with nitro-muriatic acid. This acid, in torpidity and chronic enlargement of the liver, is one of our most effective remedies. It acts by altering and promoting the biliary secretion, and by improving the tone of the digestive organs. In the chronic enlargement of liver of 'old Indians,' and in that which results from malarious poison, and also in other forms of chronic congestion, it often acts very beneficially. It may be used both internally and externally. Ten to twenty drops of the dilute acid of the pharmacopœia may be given two or three times daily, combined with taraxacum, quinine, or other drug, according to indications. The external use of the acid has been advantageously had recourse to at the Seamen's Hospital for years, either in the form of compress over the abdomen, or by sponging the surface of the body, or by the use of baths to the lower extremities. The fluid for the bath or compress is prepared by adding eight ounces of the dilute acid of the pharmacopœia to a gallon of water of about 98° Fahr. The compress may be applied by soaking a funnel roller of sufficient length, about a foot in width, in the prepared acid, and wringing it so that it merely remains damp. The roller should be then applied round the body, covered with a piece of oiled silk, and worn constantly—subject, however, to renewal of acid night and morning; or the lower extremities may be immersed in the fluid for about twenty minutes, night and morning, and the inner sides of the thighs and the body be sponged at the same time. Earthenware or wooden baths should be used, and the sponges and towels after each bath must be well washed in cold water, or they will be destroyed by the acid. At times the external use of the acid causes purging; and in several cases, at the Seamen's Hospital, severe irritation of the skin, with copious papular eruption, resulted, and the remedy had to be discontinued.

Chloride of ammonium and iodide of potassium must be mentioned as drugs that have been found serviceable in reducing livers enlarged by chronic congestion. In the hyperæmia resulting from disease of the mitral or aortic valves, or from chronic lung-changes, it is sufficient to remark that the chest-symptoms will often be most effectually relieved by treatment directed especially to the liver.

Much benefit will result in many cases of hyperæmia by a course of mineral waters at one of the German or English spas. Marienbad, the cool springs of Carlsbad, rather than the Sprudel, Kissingen, Cheltenham, Harrogate, &c., are indicated in active hyperæmia; the more tonic

waters in the more chronic forms of congestion. A more detailed notice of the different spas and waters in relation to liver-affections is given at the end of the article on Functional Disorders of the Liver. See MINERAL WATERS.

STEPHEN H. WARD.

LIVER, Hypertrophy of.—In true hypertrophy of the liver, the increase in the size of the organ is due to enlargement and multiplication of the secreting cells, without any morbid change having taken place in these, and without the deposit around them of any morbid material. The parenchyma of an hypertrophied liver is generally firm and vascular, in some few instances pale and flabby. The hypertrophy may be *partial* or *general*. *Partial* hypertrophy may either result from localised irritation of the liver, as in tight-lacing; or it may compensate for some other portion of the organ reduced or entirely destroyed by disease, as in the large irregular lobules of hepatic tissue formed in advanced cases of syphilitic hepatitis. *General* hypertrophy has been found in some cases of diabetes mellitus, in leukaemia; and, according to Dr. Jules Simon, in a certain cachectic condition produced under the combined influences of deprivation, serfism, and residence in a damp locality. Whether true hepatic hypertrophy can be caused by residence in hot climates, or by prolonged exposure to malaria, seems, according to Frerichs, to be open to doubt. It is probably due in some instances to prolonged congestion of the liver, and as a result of such a condition may occasionally be met with in drinkers and free livers, and in the subjects of pulmonary and cardiac diseases.

W. JOHNSON SMITH.

LIVER, Induration of.—The liver is commonly hardened whenever it is small. Simple induration is a state in which new connective-tissue seems to replace the proper hepatic tissue throughout large tracts of the liver. Often the organ becomes small and lobulated; at other times it is increased in size, and a case has been known in which it weighed eight pounds, constituting a connective-tissue hypertrophy of the liver. The diseased part presents the appearance of a completely homogeneous, whitish-yellow, firm, hard mass; which under the microscope is seen to be made up of connective-tissue, in which no, or very few, elements of liver-substance can be made out.

J. WICKHAM LEOG.

LIVER, Inflammation of, Acute.—SYNON.: Acute Hepatitis, *Fr. Hépatite aiguë*; Ger. *Acute Leberentzündung*.

It is usual to divide acute inflammation of the liver into *perihepatitis*, involving the investing membrane of the liver and Glisson's capsule; and *hepatitis*, in which the parenchyma of the liver is engaged—in other words, into superficial and deep-seated; but, practically speaking, perihepatitis is rarely more than an accompaniment of hepatitis, of peritonitis, or of an acute attack of a neighbouring organ. We shall not treat of the two separately, as they are constantly associated with each other.

ETIOLOGY.—Acute hepatitis is by no means a common affection in Europe, and even in the

tropics congestion is far more frequent than acute inflammation. The chief causes of hepatitis are exposure to heat, and to changes of temperature—both of which have a large share in what is called tropical influence—irregular habits of life, and spirit-drinking. Irregular action of the liver and of the bowels predisposes to it. Men in the tropics are far more subject to the disease than women or children—in fact acute hepatitis is exceedingly rare in children. The disease is uncommon in men under the age of twenty, and appears to be most frequent between the ages of twenty-five and thirty-five. Independently of the cases in which it appears to be connected with dysentery, many authors believe hepatitis to be induced by the same causes as those which produce tropical dysentery and tropical fever—in other words, by malarious influences. Hepatitis or perihepatitis are sometimes occasioned by falls, or by external violence, which may operate in producing them either directly or secondarily.

ANATOMICAL CHARACTERS.—The liver when inflamed is usually represented as softened and congested, sometimes having a granular appearance. When cut into, more blood flows from it than usual. It is sometimes infiltrated with serous fluid, with lymph, or occasionally with small spots of pus. While portions of the liver are involved in inflammation, other portions may be unaltered, but most generally it is inflamed or congested throughout, in some parts in red patches, while in other parts there are patches of a yellowish colour. These may be traced in their changes until they are converted into abscesses, which may be single, or less frequently multiple, usually these are enclosed in a cyst, which varies from the thinnest half-formed membrane to a tolerably tough one. If there has been much perihepatitis, the liver is very commonly adherent to the diaphragm or to the neighbouring viscera by organised lymph, and its capsule is thickened.

With reference to the distribution of its blood-vessels, it has been presumed that congestion of the liver is mainly caused by obstruction to the hepatic veins, consequent on affections of the heart or lungs, or by some obstruction of the vena porta, or morbid alteration of the blood which it conveys. In inflammation, again, the capillaries of the hepatic artery are believed to be primarily engorged. But these matters are not very certain. As regards suppurative inflammation, Budd maintains that it is the result of purulent matter taken up from ulcerating surfaces of the bowel, and conveyed to the liver by the vena porta.

SYMPTOMS.—These vary much in their degree of acuteness. There is frequently in the commencement chilliness, or even some shivering, followed by fever. The appetite is impaired, and there may be loathing of food. The tongue is white, and usually has a thick white coat. The bowels are sometimes constipated; more frequently there is diarrhoea. Sometimes there is great thirst, along with irritability of the stomach, with bilious vomiting. A certain degree of jaundice has been often set down as a symptom of hepatitis, but it is very unusual. There is frequently pain in the right shoulder, but by no means always. There is often aphor-

dry cough. There is generally some fever; the pulse is usually from 100 to 110, and the temperature of the body is increased two or three degrees; but there is seldom present that amount of irritation which one would expect to find, when inflammation is so acute that it may end in suppuration. In the region of the liver the symptoms are various. Sometimes there is sharp lancinating pain, especially when the convex surface is most affected; more frequently there is a dull, heavy pain, which is increased when the patient endeavours to lie on his left side. There is generally pain in the liver on pressure. On careful examination the viscous will often be found to be increased in bulk, but by no means always so. It may be enlarged upwards and backwards, or below the edge of the ribs, or towards the epigastrium. If the inflammation is at all acute, or if there be perihepatitis, which may involve the lower surface of the diaphragm, there may be shortness of breathing, which is often very distressing. The acuteness of suffering depends very much on whether the surface or the deeper portion of the organ is most involved in the inflammation. The urine is commonly high-coloured, and contains an excess of bile-pigment. Sometimes albumin is present, but on the whole nothing very definite is known on this point.

As regards the duration of the symptoms, if there only be perihepatitis, they will probably subside in three or four days. Deep-seated hepatitis may end in about ten days in resolution, or in the formation of abscess (*see* LIVER, Abscess of); or the disease may be protracted in a less acute form for weeks or months, producing enlargement or partial induration of the liver. In such cases, and indeed in the less acute form of hepatitis, it is often difficult to draw a distinction between chronic congestion and chronic inflammation.

Diagnosis.—Hepatitis is not very likely to be confounded with other affections. If the surface is particularly involved, when there is much shortness of breath, and the pains are lancinating, it may be confounded with local pleurisy or pneumonia. The auscultatory sounds, as also the position of the patient, will show whether the lungs are affected—for with pneumonia, with intercostal neuralgia, with inflammation of the stomach, or with the passage of gall-stones, he will not lie on the affected side, as in hepatitis, nor is there in these diseases the excessive irritability of stomach that there is in inflammation of the liver. The pain of gall-stones comes on more suddenly, is more acute, and disappears more rapidly. Sometimes hepatitis has been confounded with enlargement of the gall-bladder, but usually the pyriform shape and prominence of that organ when over-filled should be enough to distinguish it. As for the diagnosis between hepatitis and perihepatitis, it is chiefly of importance as regards the prognosis. The pain in the latter is usually more acute, less of a dull pain, and is less persistent. The parenchyma of the viscous is less sensitive than its surface, as has appeared to the writer, on handling and cutting off two or three inches of liver which had protruded through a wound.

Prognosis.—The prognosis of hepatitis is

grave, but its termination is generally favourable in temperate climates, especially when the case is one rather of perihepatitis than of hepatitis. In the tropics the disease is much more formidable. There is always the risk of its running into abscess; or, if that be avoided, of a state of chronic hyperemia of the organ, with enlargement and constant tendency to relapse supervening. The complication with dysentery or chronic diarrhoea is frequent and unfavourable. The ratio of mortality differs much in different places, and in the same place in different seasons; and it is difficult to ascertain the absolute mortality of hepatitis, as long as congestion and inflammation of the liver are not distinguished in statistical returns. However, hepatitis (if cholera be excluded) has long been, and continues to be steadily, the greatest source of mortality among our soldiers in India. The French found it a very fatal disease in Algiers, and it has always been one of the most serious diseases of hot countries.

Treatment.—The activity of treatment must be regulated by the acuteness of the case, and by the presence or absence of complications, such as dysentery. In former days repeated venesection used to be employed. We now find leeches applied over the liver or to the anus at least as effectual. Emollient cataplasms are to be kept constantly applied to the side. The bowels should be freely acted on with the neutral salts. The action of ipecacuanha in large doses is very useful, whether it produces nausea or operates on the bowels. It is particularly indicated when there is dysenteric complication. The general feeling is that the induction of vomiting operates unfavourably, but in the early stage of the disease we do not think a certain amount of it injurious. It seems to relieve the liver to some extent. Calomel and opium, and the exhibition of calomel in small doses, to touch the gums, was the old treatment in India; while the French trusted mainly to the exhibition of calomel, ipecacuanha, and opium. Both modes of treatment were believed to yield satisfactory results. The popular idea that if the patient was once salivated he was secure from the formation of abscess had no foundation in fact. If there is much general fever, the use of an ordinary diaphoretic mixture, with a larger proportion of tartar emetic, will be found useful; if nausea is produced, so much the better. When the symptoms become less acute, the steady use of moderate saline aperients, or of iodide of potassium—in short, the ordinary treatment for congested liver, should be adopted. Counter-irritants and blistering, or the application of tincture of iodine over the liver, are of more use in this than in the earlier stages. The nitro-muriatic acid bath has long been a popular remedy in the chronic stage of hepatitis. The body may be immersed, but a bath for the feet, or sponging the side with a solution of the acid, will usually be found as efficacious. The internal use of the mineral acids the writer believes to be more effective. Change of climate exercises a singularly beneficial effect; especially that obtained by a sea-voyage. Sudden exposure to cold, however, after a return from a warm climate, must be particularly guarded against.

The treatment of the sequelæ of hepatitis becomes practically that of congestion of the liver. The steady use of saline aperients, or a resort to the saline-alkaline, or to alkaline baths, as Carlsbad, Marienbad, Elster, Vichy and others, will be found beneficial. In the acute stage the diet must be low, and limited chiefly to fluids. Great attention must be paid to diet during convalescence also; attention to this will help materially in preventing the disease from becoming chronic, and, indeed, there is no better prophylactic against hepatitis than a carefully regulated diet, with abstinence from spirituous drinks.

J. MACPHERSON.

LIVER, Inflammation of, Chronic.—This is usually only another name for cirrhosis. Sometimes the name is given to a perihepatitis, a thickening and opacity of the capsule enclosing the liver, and beneath which the liver-substance is found hardened and tough, due to an overgrowth of the connective tissue from the capsule. Most pathologists, however, look upon cirrhosis as a chronic inflammation of the liver, and the name is usually restricted to this state. See LIVER, Cirrhosis of.

J. WICKHAM LING.

LIVER, Malformations of.—Abnormalities in the form of the liver are not common, and are more often acquired than congenital. The following are some of the most frequently observed malformations that are congenital, and due to some original defect.—A more or less quadrangular liver, a rounded liver, reduced proportions or total absence of left lobe; prolongation of the left lobe in the form of a narrow tongue-like process towards the region of the spleen; abnormal grooving of the surface of the liver; extreme depth of normal fissures. Another occasional variety of hepatic malformation consists in extensive lobulation, and the existence of one or more additional small lobes—a condition met with in the livers of rodent animals. An extreme instance of this extensive lobulation was observed by Dr. Dickinson, and is recorded in the *Transactions of the Pathological Society* (vol. xvii. p. 160). Acquired malformation may be due to hepatic abscess, to hydatids of the liver, to new-growths; to some form of chronic inflammation (cirrhosis, syphilitic disease), or, finally, to compression of the organ by tight-lacing and other means.

W. JOHNSON SMITH.

LIVER, Malignant Disease of.—DEFINITION.—Development in the liver of cancerous or sarcomatous growths, either primary, or secondary to similar growths elsewhere; causing, generally, enlargement of the organ, with irregularity of its surface; attended with pain often with jaundice and ascites, with marked cachexia and progressive emaciation; and having usually a rapidly fatal termination.

ÆTIOLOGY.—Sex has no influence in the causation of hepatic cancer; the disease occurs as often in males as in females. It is very rare in early life, but cases are recorded. Of eighty-three cases analysed by Frerichs, forty-one were between forty and sixty years of age, and the remainder in nearly equal proportions above and below that period. Climate, habits of life, over-

indulgence in the use of spirituous liquors, do not seem to play any part in determining the malady. The influence of hereditary tendency to cancer must not, however, be overlooked.

ANATOMICAL CHARACTERS.—The malignant growths which affect the liver are usually the carcinomata—the true cancers; and of these, in nearly all cases, the scirrhus or medullary or encephaloid forms, the colloid being rarely met with, and then only as a secondary deposit. Of the sarcomata, the melanotic and round-celled or medullary sarcomata are met with occasionally. Cancer may occur as an infiltration of the liver-tissue, when large masses of the liver are uniformly affected, and little or no irregularity of surface results. It usually, however, occurs in circumscribed masses, smaller nodules or larger protuberances, varying in size, to use a familiar comparison, from that of a pea to that of a child's head. These masses are more or less numerous, and usually distinct; or they may encroach upon one another, and give an appearance of coalescence. When near the surface, they give rise to the marked irregularity which is very characteristic of the disease; and when large and numerous, cause considerable increase in the size of the liver. The masses on the surface are sometimes flattened, and have a central depression which has been designated as 'cancer navel.' The growths may be firm and of brawny or even cartilaginous consistence, as when scirrhus prevails, or they may be of medullary softness, when an incision will yield freely the so-called cancer-juice. The cut surface is either white, or reddish-white, or darker red when blood has been recently extravasated, or of varying colour, from altered blood-pigment, when the extravasation of blood has been of longer date. The portal and hepatic veins are sometimes invaded by the cancer, and a clot is formed in them, which becomes cancerous. Colloid cancer of the liver occurs rarely as a secondary invasion from the stomach or peritoneum. Melanotic sarcoma or melanosis exists occasionally in conjunction with the disease in other parts of the body. Malignant disease of the liver is primary in about one-fourth of all cases; secondary in the remainder, and in about one-half of the cases in which it is so, the primary disease has been seated in structures connected with the portal system.

SYMPTOMS.—In the earlier stage of this disease, the symptoms may be merely subjective, and then diagnosis will be difficult. When the disease, however, is far advanced, a prominent irregular swelling may be seen, raising the abdominal parietes, and occupying often a large portion of the abdominal cavity. Lesser grades of the disease may be detected by palpation and percussion. The liver will be found to extend more or less beyond its normal limits; to be hard and resisting, and, in a large proportion of cases, irregular. In a few cases, however, when the disease is infiltrated, the surface will perhaps be smooth throughout. At times there is no enlargement of the organ, and the portion affected lies under the ribs, so that physical examination does not help us. There is often tenderness on pressure, especially when the peritoneal coat is inflamed. Usually, but not always,

there is pain in the liver itself; sometimes merely a feeling of tightness and fulness; at other times a gnawing, aching pain; and some patients have described the pain as 'burning.' There is frequently also pain shooting back to the spine, over the sacrum, or about the angle of the right scapula. A sensation as of a cord drawn round the right hypochondrium has been complained of. There is sometimes pain radiating down to the lower part of the abdomen, and occasionally wandering pains in the extremities and body generally are complained of. When the stomach is intact, there may be no material disturbance of its functions, but usually derangement is manifested by loss of appetite, nausea, vomiting, and other symptoms, which will be intensified if the stomach is implicated in the disease. The bowels are, as a rule, constipated in the earlier stage, but towards the close there is often dysenteric diarrhoea. Jaundice occurs in nearly one-half of the cases of malignant disease of the liver, and is due to compression of the bile-ducts by cancerous masses within the organ, or by an enlarged lymphatic gland in the portal fissure. When once established it is permanent, and the colour of the patient varies, being pale yellow, or deep olive-yellow, or greenish, or sometimes of the dark hue which has given rise to the term 'black jaundice.' The stools in such cases are white or clayey in appearance; and the urine deep-coloured from bile-pigment. The condition of urine, when there is no jaundice, is variable; in the earlier stages of the disease it is generally scanty and pigmented, and loaded with lithates, in the last stage, according to Dr. Purkes, copious, pale, and deficient in urea. This condition he attributes to the utter failure of digestive and nutritive power. Ascites is present in more than half of the cases, and is due either to compression of the portal vessels, or to inflammation of the peritoneum. Sometimes the large size of the tumour, especially if ascites to any extent be present, may cause much pressure upwards, and give rise to distressing chest-symptoms, such as embarrassed breathing, or palpitation. Hemorrhage not unfrequently occurs in advanced cases. The blood may come from the stomach or bowels, and be due to portal obstruction; or may be of passive character, as in scurvy or purpura; and the bleeding may take place beneath the skin, or come from the stomach or bowels. In the latter case the hemorrhage is accompanied, according to Frerichs' experience, by intense jaundice, and usually by somnolence and delirium. The complexion of patients suffering from the disease under consideration, when there is no jaundice, is usually pallid, anæmic, earth-coloured. There is, in a large majority of cases, progressive, and towards the close, often extreme emaciation. Generally there is no fever, but a sort of hectic may occur when the cancerous development goes on rapidly, and involves several organs. When the disease of the liver is secondary to, and complicated with cancerous affections of other organs, as the stomach—which occurs in a considerable proportion of cases—prostate, uterus, or mammary gland, symptoms will be indicating such complications, but need not be specially dealt with here.

Diagnosis.—When hepatic cancer is somewhat

advanced, and the liver large and irregular on its surface, the diagnosis will be easily effected. In the early stage, on the contrary, and in cases in which, throughout, the liver is not perceptibly enlarged, one must be cautious in giving a hasty or too decided opinion. Inherited tendency to cancer, the age of the patient; in women the period of 'change of life,' a mallow, earthy aspect; progressive emaciation; and pain in the right hypochondrium, point with fair probability to the disease. But nearly the same conditions and symptoms may be associated with aggravated hypochondriasis, or chronic tendency to gall-stones; and in the latter case, the difficulty of diagnosis is increased, as gall-stones are often associated with cancer. Permanent closure of the bile-duct from other causes gives rise to persistent jaundice and other symptoms, as in the case of closure by pressure from a cancerous mass. Enlargement of the liver from malignant disease may be confounded with the following hepatic enlargements and malignant tumours:—

- 1 **Albuminoid or lardaceous disease.** In this affection the hard, perfectly smooth surface, with preservation of normal shape of the liver, absence of pain in the tumour, and of jaundice, will be sufficiently distinctive, unless the liver is rendered somewhat uneven by other associated affections.
- 2 In a not very advanced stage of cirrhosis, as also of malignant disease, the liver may be enlarged, and its surface uneven, and in both diseases there is great resemblance in the aspect and general cachectic state of the patient, and similar disturbance of gastric and hepatic function. In cancer, however, the ascites is generally but slight, and the liver, instead of contracting, as it usually does in cirrhosis as the disease progresses, continues to increase, and is marked by large nodules and protuberances, which contrast with the smaller elevations in cirrhosis. In cancer the skin is often perspiring; in cirrhosis it is harsh and dry. Intemperance is not an element in the etiology of cancer, as it is in cirrhosis. In the latter disease, as also in lardaceous liver, the spleen is frequently enlarged.
- 3 Hydatid tumour is to be distinguished from a localised cancerous mass by the presence of more or less distinct fluctuation; and the absence of pain, and of serious functional and constitutional symptoms.
- 4 A tumour caused by hepatic abscess would probably give evidence of fluctuation; be associated with or consequent upon dysentery; and often attended by rigors, hectic fever, and characteristic shoulder-tip pain.
- 5 Malformations and malpositions of the liver have been mistaken for cancerous enlargement, especially in females about the period of 'change of life.'
- 6 A highly-distended gall-bladder has been mistaken for a cancerous projection from the liver; but the smooth, oval swelling, and the site of the enlargement, are distinctive, and, as Frerichs says, a practitioner who made an erroneous diagnosis in such case would be wanting in the *tactus eruditus*.
- 7 Cancer of the omentum would present a movable tumour, separable, probably, from the liver by a slight area of tympanic resonance.
- 8 Cancerous deposits in the left lobe of the liver may be readily mistaken for cancerous affections of the stomach.

The following points will assist in diagnosis—

(a) Percussion in the greatest thickening of the stomach-walls gives a tolerably clear, tympanitic sound; in cancer of the left lobe of the liver, the sound is much more deadened, and is only somewhat tympanitic on stronger percussion stroke; (b) careful examination of the liver, and of the stomach, when full and when empty, will also lead to a correct conclusion; (c) even when the liver and stomach are both affected, careful examination may often make out the boundaries of disease in each. 9. Malignant tumour of the right lobe may be mistaken for malignant enlargement of the right kidney. Percussion will generally give a tympanitic sound, from the presence of intestine between the kidney and liver. The hepatic tumour is also distinguished from this and other abdominal tumours by its following the movements of the diaphragm in respiration. But when the renal enlargement is very great, diagnosis is not easy. Three or four years ago a sailor was brought into the Seamen's Hospital with an immense tumour occupying the greater part of the abdomen. This was diagnosed by all who saw it as malignant disease of the liver. After death, however, it was found that the liver was quite healthy, much compressed and narrowed, and spread out over the upper part of an enormous, cancerous kidney. 10. Malignant disease of the ascending or transverse colon will constitute a movable, and generally somewhat tympanitic swelling; and faecal accumulations in the colon may be removed, but not always readily, by aperients and injections. Percussion, too, will often elicit a resonant space between the enlarged intestine and the liver.

PROGNOSIS.—The prognosis is always unfavourable. The disease when once fully pronounced runs its course rapidly, the fatal termination being seldom deferred beyond a year. Schirrus has usually a longer duration than medullary cancer.

TREATMENT.—This can be but palliative, and directed to rendering the inevitably fatal course as smooth as possible, by relieving distressing symptoms. Remedies which in other hepatic affections are valuable, such as chologogues, or mineral waters, are here useless, if not worse. The diet should be plain and nourishing, and the moderate use of wine and alcohol is not contraindicated, as in other disorders of the liver. Serious gastric and other derangements must be met by appropriate remedies, it being always borne in mind that we have to soothe the patient, and not add to his distress by the exhibition of nauseous drugs. For the relief of pain, the various preparations of opium are indicated, and, as a rule, morphia acts the best. It may be administered either internally, or by the hypodermic method, and must be repeated when pain demands it. Local applications over the liver, as poultices, spongio-piline, &c., with solution of opium sprinkled over the surface, are useful, especially when the peritoneal coat is inflamed. Tapping should not be had recourse to for the relief of ascites, unless this becomes so great as to interfere by upward pressure with the functions of the lungs or heart. The fluid soon reaccumulates, and the effect of the operation is to hasten the fatal termination.

STEPHEN H. WARD.

LIVER, Malpositions of.—Abnormalities in the position of the liver are much less rare than abnormalities in its form. The more frequent forms of congenital displacement are these: Lateral transposition, the liver being found on the left instead of the right side of the abdomen; eversion, the organ being exposed in front of the abdomen of a fœtus; the presence of more or less of the liver in the chest, through congenital deficiency of the diaphragm. In *acquired* displacement the liver may be either depressed or elevated, some rotation of the organ on its transverse axis taking place in an opposite direction in each case. Depression may be caused by pressure from above, as by effusion in the right pleural cavity, and probably to some slight extent by considerable pericardial effusion, or cardiac hypertrophy. Elevation of the liver, which takes place more frequently, may be due to pregnancy, ascites, or the presence of some large abdominal tumour. Curvature of the spine, whether lateral or angular, usually gives rise to some change in the position of the liver. In Potts' disease the organ is often forced downwards towards the crest of the right ilium.

By tight lacing both the position and the form of the liver may be altered. The organ may be forced downwards, and at the same time so twisted on its transverse axis that its convex surface looks directly forwards, and its concave surface directly backwards. When tightly compressed the upper surface of the right lobe becomes marked by the ribs, and presents transverse puckering. At the same time the right lobe is bent upon itself, the concavity of its lower surface being much increased. The hepatic tissue corresponding to the summit of the arch thus formed gradually wastes, until at last the lobe is divided into two portions by a deep transverse groove, which portions are connected merely by a membranous band, composed of thickened serous membrane, and the corresponding portion of the hepatic capsule.

W. JOHNSON SMITH.

LIVER, Morbid Growths of.—Several morbid growths have been met with in the liver, of which the following are the most important:—

1. **Simple Cysts.**—These formations are not often met with in the liver. There may be a single cyst, which is usually large; or a number of small cysts scattered throughout the organ. In the latter case the condition is analogous to that of the so-called cystic disease of the kidney, and indeed is sometimes associated with this affection. The cyst-wall consists of a fibrous membrane projecting in folds into the cavity of the sac, and lined on its inner surface by pavement-epithelium. The cyst almost always contains thin clear fluid, and is not connected with any bile-duct or vessel.

2. **Dermoid Cysts.**—Mr. Hulke has recorded an instance in which several dermoid cysts in a withered condition were found attached to the surface of the liver.

3. **Breastlike Tumours.**—An hepatic scirrhus or cavernous tumour consists of a small red or bluish-red formation, of a more or less globular shape, of reticulated structure, and containing

fluid blood or soft coagula. Growths of this nature are often multiple, and each of about the size of a filbert; they are usually found either along the anterior margin of the liver, or on the upper surface of this organ, near the attachment of the suspensory ligament. Each tumour is enclosed in a capsule of delicate connective-tissue. Though seated at the periphery of the liver, an erectile tumour seldom projects beyond the surface of the organ. Much remains to be made out as to the pathological significance of these tumours, especially with regard to their relation to malignant disease. There is some difference of opinion as to their connection with the hepatic vascular system. Virchow and Wilks hold that they are in communication with minute branches of the hepatic artery; whilst Frerichs states that they cannot be injected through this vessel or through the hepatic veins, but only through branches of the portal vein.

4. Lymphatic Formations.—The liver is sometimes found studded in all parts with minute patches of tissue of soft consistence, each patch being made up of an aggregation of lymphoid cells disposed in the meshes of a delicate reticulum. These patches of tissue are in close connection with small vessels, from the walls of which, according to Frerichs, they are developed. This condition is associated with leukaemia.

5. Tubercle.—Tubercle, as met with in the liver, occurs only in the form of minute miliary granulations, scattered throughout the whole organ, but accumulated more especially on the surface. These growths have been rarely observed in the liver, and in most of the instances in association with acute general tuberculosis.

6. Cancer.—Different forms of cancer are liable to affect the liver; but this class of diseases is so important that they require separate consideration. See LIVER, Malignant Disease of.

7. Hydatids.—This is an important disease affecting the liver, which demands notice in this connection, but it is discussed in a separate article. See LIVER, Hydatids of.

8. Benign Growths.—Fibrous and other growths have been in rare instances found in the liver, but they do not give rise to any clinical signs. W. JOHNSON SMITH.

LIVER, Nutmeg.—SYNON.: *Fr. Foie noir des saoude; Ger. Mucosinsulecher.*—Nutmeg-liver consists in a chronic passive congestion of the organ, a state which may always be brought about when there exists any impediment to the circulation of the blood through the heart or lungs. The radicles of the hepatic vein become filled with blood, and thus the centre of each acinus shows a deep red, while the outer parts are either yellow or of natural tint. A nutmeg appearance is thus given to the liver, which is often shrunken and tough, with adherent capsule, and granular surface. Under the microscope the centre of the acinus is seen to be filled with dilated blood-vessels, which, pressing on the liver-cells, cause them to atrophy, so that in advanced stages of the disease they disappear altogether, and the centre of the acinus is made up of blood-vessels

only, but there is no increase of the connective tissue in the same situation. The capsule of Glisson now and then takes on an overgrowth, just as in cirrhosis; and the connective tissue between the lobule and around the vessels is considerably increased. It is to this overgrowth of the connective tissue that the shrinking and hardening of the liver are due.

SYMPTOMS.—The liver may sometimes be felt during life under the ribs, more often not. Slight jaundice is often present. The spleen is not enlarged, but is small—the opposite condition to that found in cirrhosis.

TREATMENT.—This must be directed to the condition of the heart or lung upon which the obstruction to the circulation depends. Nutmeg-liver may always be suspected when there exists any impediment to the return of blood from the hepatic veins J. WICKHAM LEOG.

LIVER, Pigmentation of.—In subjects who have succumbed to intense malarious fever, and in some who during life had suffered from frequent attacks of intermittent or remittent fever in hot climates, the liver may be found to be stained by pigment, either diffused throughout the whole organ, or dispersed here and there in irregular patches. This pigmentation of the liver is always associated with a similar condition of the spleen, and frequently with staining of the nervous centres, the lungs, the kidneys, and the lymph-glands. Hepatic pigmentation is one of the chief post-mortem phenomena of the condition known as ‘melanæmia,’ in which the blood, especially that of the portal system, is pervaded by granules of pigment of a black or deep-brown colour, some of which are free and isolated, some held together in irregular masses by a pale jelly, and others enclosed in cells. In the pigmented liver these granules are to be found in the portal blood, in the walls of the capillaries, and outside the vessels, scattered amongst the hepatic cells, but not within those cells. In an early stage of the hepatic pigmentation the staining affects only the periphery of each lobule, but, as the disease progresses, the deposit gradually extends to the centre of the lobules, and attacks the hepatic venous system. The arterial capillaries also contain similar pigment-granules.

SYMPTOMS.—The size of the affected liver varies in different cases, and according to the severity and the stage of the disease. The organ is sometimes congested and swollen; it often remains of normal size; in some few instances it finally becomes atrophied. The main symptoms of this condition of the liver are occasional intestinal hæmorrhage, diarrhoea, and ascites. These symptoms in well-marked cases of melanæmia are usually associated with albuminuria, due to pigmentary affection of the kidneys, and with more severe symptoms due to cerebral complications, such as delirium, coma, and paralysis. Melanæmia has been met with mostly in warm climates, and occasionally during severe epidemics of intermittent and remittent fever in some parts of the North of Europe. In this country it has been very rarely observed. See BLOOD, Morbid Conditions of.

W. JOHNSON SMITH.

LIVER, Syphilitic Disease of.—The liver

occasionally becomes diseased during the tertiary stage of syphilis, or the period of gummy deposits, the hepatic affection being associated at some period with osseous and cutaneous lesions, and with syphilitic cachexia.

ANATOMICAL CHARACTERS.—*Syphilitic hepatitis* may attack both the capsule (*perihepatitis*) and the internal prolongations or septa of the capsule (*parenchymatous hepatitis, syphilitic cirrhosis*). In some cases a small portion, in others a greater part or the whole of the organ, is affected. In the milder form and less advanced stages of the disease the capsule is slightly thickened, and marked by a few isolated white patches, while the surface of the liver is here and there slightly grooved and indented. After prolonged inflammatory action the liver becomes much deformed, and is made up of a number of small lobes bounded by deep depressions, the parenchyma on section being found to be traversed by well-marked bands of tough and retractile connective-tissue. The secretory structures of the liver do not undergo very much change in this disease, and notwithstanding the retractile properties of the fibrous tissue forming the white bands, the vessels and ducts usually remain permeable. The liver-cells occasionally become loaded with fatty elements, and in some rare instances undergo albuminoid degeneration. In cases of syphilitic hepatitis, the liver is almost always bound to the diaphragm, and sometimes to the adjacent viscera, by firm adhesions.

Deposition of *gummy tumours*—‘the encysted knotty tumours of the liver,’ as they were named by Dr. Budd—occurs more frequently than syphilitic hepatitis, with which condition, however, it is often associated. In this form of syphilitic disease, the liver presents on section, especially in its deeper parts, a number of globular growths, more or less firm in consistency, of a yellowish-white colour, and varying from the size of a pin's head to that of a large walnut. A large deposit of this kind is usually soft or cheesy at its centre, and becomes more and more firm towards its periphery, where it is surrounded by a greenish and translucent zone of incipient connective-tissue, which passes gradually into apparently healthy parenchyma. A full description of the minute structure of these hepatic gummy tumours will be found in a report by Dr. Payne on three specimens shown before the Pathological Society in 1870 (*Transactions of the Pathological Society*, vol. xxi. p. 207). In each tumour it was found that the soft central portion was composed of granular and almost amorphous material, in which were imbedded certain round or irregular translucent bodies of large size, which probably represented collections of degenerated liver-cells. The soft central portion passed imperceptibly into fibro-nucleated structure. The surrounding fibrous zone was found to be composed of dense connective-tissue, in crescentic and irregularly-shaped interspaces, containing masses of fatty globules or granular matter. This fibrous structure was not strictly defined from the structure of the more central parts of the tumour, and on the outside passed into the interstitial connective-tissue of the liver, and became converted into masses of nucleated tissue each of which masses

appeared to be formed around a small branch of the portal vein or hepatic artery. Dr. Payne supports the view held by Virchow concerning the pathogenesis of hepatic gummy tumours, and holds that the amorphous central portion is to be regarded, not as a deposit of tissue slowly organised from the first, but as fibrous tissue in a more or less advanced stage of involution and decay.

Whether true *hepatic cirrhosis* may be caused by syphilis is open to doubt, since in most cases supposed to be of syphilitic origin it has been found impossible to exclude with confidence the idea of a probable alcoholic origin.

Albuminoid degeneration of the liver has not unfrequently been observed in the subjects both of acquired and of inherited syphilis, and very often in syphilitic subjects who had not been previously affected with caries or necrosis of bone, with cutaneous ulceration, or with profound or prolonged suppuration. This condition of the liver, when associated with syphilis, is probably due rather to cachexia and debility, than to any essentially syphilitic influences. The almost if not quite obsolete views that the amyloid disease is to be attributed to the action of mercury, or to the combined action of this medicinal agent and syphilis, are opposed by the facts that this condition of the liver has often been observed in a syphilitic fœtus, and also in adults who had not previously been treated with mercury, and never in non-syphilitic subjects of mercurial poisoning.

SYMPTOMS.—The symptoms of syphilitic hepatitis and gummy tumours in the liver are in most instances obscure, so that these complications of advanced syphilis are often overlooked. The liver in some cases is enlarged, in other cases reduced in size. In the former instances it will often be found on abdominal percussion that the relative proportions of the right and left lobes have been much altered, and that there is considerable deformity of the whole organ. Firm globular elevations on the surface of the liver may sometimes be felt through the anterior abdominal wall. Advanced syphilitic hepatitis is usually associated with slight and slowly increasing ascites, and sometimes with œdema of the lower extremities. There is seldom any well-marked jaundice. The patient often complains of a sense of weight and uneasiness in the right hypochondrium, or, in some few cases, of severe pain. In almost all cases there is some hepatic tenderness. The most constant symptoms are of a dyspeptic character; the abdomen often becomes painful and distended; and there is very often, at an advanced stage of the disease, obstinate and profuse diarrhoea.

DIAGNOSIS.—The slow progress of the disease; the absence of any severe pain in the region of the liver; a clear history of syphilis, and the presence of syphilitic lesions at some part of the body; no history of cancer; and the absence of any indications of malignant disease, whether on the surface of the body or in the abdominal cavity, all serve to support the diagnosis of syphilis, as opposed to cancerous disease of the liver. In ordinary cirrhosis of the liver the progress of the disease is more rapid; the dyspeptic symptoms more severe; the ascites more abundant; and the indications of alcoholism are generally well marked.

TREATMENT.—The treatment of syphilitic disease of the liver is that usually carried out in cases of tertiary syphilis.

W. JOHNSON SMITH.

LIVER, Tubercular Disease of. See LIVER, Morbid Growths of.

LIVER-FLUKE.—A common name for the *Flasciola*. See DISTOMA.

LLANDRINDOD, in Radnorshire, South Wales.—Saline, sulphated, and chalybeate waters. See MINERAL WATERS.

LOBULAR (*lobulus*, a little lobe).—Of or belonging to a lobule. A term generally applied to morbid conditions affecting individual lobules of organs which are thus constituted, such as *lobular pneumonia*, *lobular pulmonary collapse*, and *lobular hepatitis*.

LOCAL.—This term is used in contradistinction to the word *general*. Thus, in connection with *morbid conditions*, it is applied to those which are confined to, or seem specially to affect, a particular part. Again, *local causes* are such as act upon a limited portion only of the body, such as a blow or a burn. *Local treatment* implies the application of remedies in the same sense.

LOCK-JAW.—A popular synonym for tetanus. See TETANUS.

LOCOMOTOR ATAXY (*loca*, a place, and *motus*, I move; & *priv.* and *radix*, order).—SYNON.: *Tuber dorsalis*; Fr. *Ataxie locomotrice*; Ger. *Graue Degeneration der Hinterstränge des Rückenmarks*.

DEFINITION.—A disease of the spinal cord, characterised by a peculiar unsteadiness in the performance of voluntary movements, or a loss, to a greater or less extent, of the power to control and co-ordinate the action of muscles necessary for the steady performance of these movements.

ÆTIOLOGY.—The causes of locomotor ataxy are so various, that in persons who are predisposed to it, almost anything that seriously depresses the nervous power, especially of the spinal cord, will become an exciting cause. Such are cold, wet, excessive fatigue, bad or insufficient diet, depressing emotions of the mind, and, as the writer thinks, onanism, or the long continuance of other forms of sexual excess. Suppression of habitual perspirations, particularly of the feet, and the removal of hemorrhoids, have in many instances immediately preceded the disease. But prolonged exposure to cold and wet appears to be one of its most common causes. Syphilis is regarded by some as the chief predisposing cause; and the disease is certainly very much more frequent in males than in females.

ANATOMICAL CHARACTERS.—The spinal cord is invariably altered in structure. Generally, the membranes are much congested, and the writer has often found them thickened posteriorly by medulations, and adherent to each other and to the posterior columns. The posterior columns, especially in their outer regions, and the nerve-roots are the parts that are chiefly affected. The principal change consists of atrophy and disintegration of the nerve-fibres, to a variable extent; and hypertrophy of the connective tissue. Oil-

globules surround many of the blood-vessels. The posterior nerve-roots undergo the same kind of degeneration, which sometimes extends to the surfaces of the lateral columns, and even along the edges of the anterior. Sometimes the writer has found the extremities of the posterior cornua, and even the central gray substance, more or less damaged by disintegration. The pathological change seems to travel from the centre to the periphery—from the spinal cord to the posterior roots. In the cerebral nerves, however, the morbid change takes an opposite direction—from the periphery towards the centres. Sometimes it extends as far as the corpora geniculata, but seldom as far as the corpora quadrigemina.

SYMPTOMS.—In most cases the unsteadiness begins in the lower extremities; but generally—after a certain but variable time—it involves the upper extremities, the hands and arms being the parts most affected.

As the writer has pointed out, this unsteadiness, or muscular inco-ordination, occurs under two consecutive forms. It first makes its appearance as a simple unsteadiness of gait; the patient walks like a person partially intoxicated. He likewise frequently complains of heaviness in his legs, and of fatigue after walking or after standing. With his legs close together, and his eyes shut, he sways about and would fall if not supported. Later on he finds that he cannot walk without looking at his feet. When the upper extremities become affected, the patient is unable to dress himself, to button his clothes, to write, or to pick up a pin.

After a time a second kind of disorderly movement supervenes. This arises from a spasmodic and jerking action of the muscles, which the will puts in motion, but is unable to control; the patient cannot regulate the *degree of their contraction*. When put in motion the muscles contract beyond the degree intended, and flex or extend the limb with an uncontrollable jerk. All the voluntary movements are hurried and precipitate. The patient seems to be walking upon springs, he proceeds with a kind of prancing gait, and brings his heels to the ground with a kind of kick. If he attempts to take hold of an object he probably will thrust it from him by a spasmodic jerk of his arm. The disease is progressive. At an advanced stage the patient cannot walk or stand without assistance, and even then, if he attempts to advance, he jerks his legs about in the most disorderly manner.

The ataxy or disorderly movement is accompanied by some of the following symptoms, namely:—Strabismus, diplopia, amblyopia, anisotropia, ptosis, contraction of both pupils or only of one; shifting pains in different parts of the body, but chiefly in the extremities; cutaneous and muscular anæsthesia, and loss of the sense of temperature; incontinence of urine, and dysuria; loss of electro-muscular contractility, in a variable degree; abolition of the patellar-tendon reflex; spermatorrhœa, with loss of sexual power and desire; occasionally, but not often, paralysis of the first, fifth, seventh, eighth, and ninth cerebral nerves; œdematous swelling of the joints, chiefly of the knees; and cardiac and gastric disturbance.

All these symptoms are never found together in any one case of locomotor ataxy, but occur in different groups in different cases, as the following examples will show. The symptoms made their appearance in the order of time in which they are mentioned.

Case 1.—Strabismus and diplopia; pains in the legs, with numbness of toes, ataxy, or unsteadiness of gait; numbness of fingers, followed by pains in the arms, with unsteadiness of muscular movements; incontinence of urine; both pupils contracted to the size of pins'-heads.

Case 2.—Darting and shifting pains in legs, with numbness and heaviness, pains in abdomen and chest; ataxy; pains and numbness in hands and arms, followed by ataxy; analgesia, incontinence of urine, alternating with dysuria, hæmorrhoids; loss of sexual power.

Very frequently the pains in the limbs are, for a variable period, the only precursors of the other symptoms. They are of two kinds—the first is of an aching, gnawing character, and is often mistaken by the patient for rheumatism. The other kinds of pains are acute and lancinating, like electric shocks, shifting from one part of the body to another. They recur in paroxysms, lasting for a few hours or a few days, and suddenly disappear for a variable period.

In other cases the ocular disturbances are the first symptoms that make their appearance. They consist of strabismus, or amblyopia, ending frequently in amaurosis. In a large proportion of cases, paralysis of either the third or the sixth cerebral nerve, with diplopia, is found during the first stage of the disease. The peculiarity of this paralysis is its periodicity. It may last for a few days, or a few weeks or months, and then disappear as suddenly as it came, or it may continue uninterrupted throughout the disease. Sometimes the strabismus is double, but more frequently it is limited to one eye. Even when there is no perceptible strabismus, there is sometimes double vision, when the patient turns his eyes in a particular direction. Ptosis and dilatation of the pupil are also frequently present. In some cases one pupil is dilated, while the other is contracted. Amblyopia sometimes appears at a very early period, and increases till it terminates in amaurosis.

Cutaneous anaesthesia usually accompanies the ataxy, and affects chiefly the arms, fingers, legs, and toes. The patient says that he seems to be walking on something soft, and does not feel the ground properly; unless he looks at his feet, he scarcely knows that they have reached it. Sometimes he feels as if he were 'walking on air,' on his ankle-joints, or on his hip-joints, when the numbness extends up the legs and thighs. Analgesia, or loss of sensibility to pain, in a greater or less degree, is very common; or painful impressions are felt with unusual slowness. The writer has known cases in which several minutes have elapsed before the prick of a needle has been felt.

Disorders of the urinary organs are generally intermittent in their attacks. Usually the dysuria and incontinence recur alternately in the same stage of the disease. Spermatorrhœa is commonly one of the early symptoms in locomotor ataxy. It is followed by loss of

sexual power, with or without loss of sexual desire.

Affection of the joints in locomotor ataxy was first described by M. Charcot, of Paris. The knee-joint is almost always the seat of the disease, which appears suddenly as an elastic oedematous swelling. Like the diplopia, strabismus, and urinary troubles, it may be intermittent—may remain only for a short time, or continue uninterruptedly and result in permanent deformities, with disease of the bones and cartilages of the joint.

The strabismus, amblyopia, and shifting intermittent pains were considered by Duchenne as the first stage of ataxy, which may last for months or years. The next stage is when the ataxy or unsteadiness of gait makes its appearance, either accompanied with or soon followed by anaesthesia or analgesia, generally in the lower extremities. In the third stage many of the symptoms become more marked and more general, the ataxy or muscular inco-ordination extending to the upper extremities. This division into three distinct stages does not, however, apply to all cases.

DIAGNOSIS.—In the early stages of the disease, especially before the muscular ataxy has made its appearance, and when only two or three other symptoms are present, the diagnosis is extremely difficult, even to those who have great practical experience of the disease. Several of the symptoms, such as strabismus, amblyopia, anaesthesia, and the so-called 'rheumatic' pains, which precede frequently for a long time the motor ataxy, may be found in other disorders which differ essentially from this malady. But there is often in some of these symptoms a certain peculiarity which may assist us in the diagnosis. For instance, in a great many cases the strabismus is accompanied by amblyopia, and when it is single, the amblyopia is on the corresponding side. Moreover, the sudden attacks and equally sudden cessation of the pains, their rapid shifting from one place to another, or their remarkable proneness to fix, sometimes for hours, on some particular spot, are not without their significance.

PROGNOSIS AND TREATMENT.—The prognosis is generally very unfavourable. An early diagnosis is of the greatest importance, as it is chiefly at the first invasion of the disease that the patient is most benefited by treatment. An important object is to protect the patient from cold and wet and keep him in an equable temperature. The whole of the body should therefore be enveloped in flannel. A good and generous diet, with wine or beer, seems best suited for the patient. Of the different medicines that have been used, nitrate of silver seems to have the most specific influence on locomotor ataxy. One-eighth of a grain gradually increased to one grain three times a day, after meals, is the best mode of exhibition. If it should irritate the bowels or the bladder, it may be combined with morphia, cannabis indica, or belladonna. The oxide of silver is a useful substitute for the nitrate, when the latter disagrees. Dry-cupping along the spine has been found useful. For the relief of the severe limpains there is nothing so efficacious as the subcutaneous injection of morphia. The writer has

always found that constipation aggravates the pain. Sulphur baths have been used with some relief. Cod-liver oil and phosphorus may also be prescribed. Rest has been strongly recommended; and the constant galvanic current is certainly sometimes beneficial.

J. LOCKHART CLARK.

LORDOSIS (*Λορδός*, bent).—A term applied to abnormal curvature of the spine forwards. See *SPINE, Diseases of*.

LUCID INTERVALS.—No better definition of this state has been given than that of Lord Thorlow, who calls it 'an interval in which the mind having thrown off the disease had recovered its general habit.' It must be regarded as extremely unlikely that a perfect restoration to reason can take place in the course of any long-continued insanity, without full opportunity having been afforded of testing its nature. The law more readily recognises the restoration of the mind to a state of civil capacity such as will render testamentary acts valid, than such temporary recovery as would restore responsibility for crime. If a civil act be rationally performed, the law accepts that as *prima-facie* proof of the capacity of the agent, but juries very seldom convict the accused of a crime if insanity is proved to have existed within a short period of its commission.

JOHN SINHAID.

LUHATSCHOWITZ, in Moravia.—Mineral alkaline waters. See *MINERAL WATERS*.

LUMBAGO (*lumbi*, the loins) *SYNON* *Fr. Lumbago*; *Ger. Lendenweh*.—Muscular rheumatism, affecting the muscles and fasciæ of the lumbar region. See *RHEUMATISM, MUSCULAR*.

LUMBAR ABSCESS.—**DEFINITION.**—A variety of spinal abscess, usually due to caries of the upper lumbar or lower dorsal vertebrae, in which the pus, instead of taking the course followed in psoas abscess, becomes enveloped by the muscles and fasciæ of the lumbar region, and usually points in this situation; or by infiltrating the cellular interspaces of the abdominal muscles, gains the front of the abdomen, and descends above Poupart's ligament. The last-named feature is a diagnostic point of some moment, since psoas abscess, although commencing in the same manner, is usually characterised by making its way below Poupart's ligament.

ÆTIOLOGY.—The origin of lumbar abscess is often ascribed by the patient to a wrench or a blow—statements which must be taken with some caution, since it will be noticed that the patient rarely remembers any injury having happened, until long after well-marked symptoms have arisen. Curvature of the spine is almost invariably present. In children it is almost always the result of serofulous osteitis; and it has been by some ascribed, in adults, to sexual excesses.

DURATION.—Lumbar abscess may commence in the soft parts, but when dependent on spinal caries is preceded by the usual symptoms of Pott's disease, which have been coming on slowly and insidiously for a period varying from three to six months.

Owing to the numerous tendinous expansions,

and dense aponeurotic structures and fasciæ of the lumbar region, the pus, which has formed in connection with the spine, meets with many obstructions, resulting in singular deflections, before it gains the surface (see *LUMBAR FISTULA*). Most frequently it perforates the quadratus lumborum muscle, and points at the edge of the sacro-lumbalis. Here it shows itself as a broad, flat, slightly elevated, fluctuating tumour; having a somewhat irregular surface, owing to the tendinous structures which traverse its cavity. Occasionally the pus of a lumbar abscess makes its way downwards and forwards above Poupart's ligament, or between the abdominal muscles, and points at the outer edge of the rectus abdominis muscle, and indeed there would seem to be no intermuscular or interaponeurotic space which it may not permeate. In other instances, it may be first observed by palpation of the abdominal walls, may simulate cecal abscess, a malignant growth, an intestinal collection, an aneurysm, or other abdominal tumour; or may burst into the cellular tissue of the abdominal cavity. In children, owing to the relatively small size of the pelvis, there is a chance of the pus mounting over the iliac crest, or sideways over the glutei muscles.

PROGNOSIS.—The prognosis is precisely the same as that mentioned in the article on psoas abscess. See *PSOAS ABSCESS*.

TREATMENT.—The treatment is the same as that indicated in psoas abscess, namely, free antiseptic incision. There are, however, cases where spontaneous evacuation of the pus, and treatment by the prone couch have led to good results, and, moreover, there are cases of spontaneous cure.

EDWARD BELLAMY.

LUMBAR REGION.—This region, to which it is somewhat difficult to assign precise limits, may conveniently be described, for practical purposes as bounded (with reference to the surface of the body) superiorly by the last rib, below by the posterior half of the upper edge of the crest of the ilium, and externally by the posterior margin of the external oblique muscle. The series of lumbar spines would thus superficially separate the right from the left lumbar region. All the structures lying between the skin and such abdominal viscera as are in relation with the parietes, enter into the formation of the lumbar region, the symmetry of the two sides being broken by the fact that the right kidney lies lower than the left. These structures are met with in the following order from the surface:—

1. the skin; 2. the cellular tissue; 3. the lumbar aponeurosis; 4. the musculo-aponeurotic layer, 5. the bones; and 6. the visceral layer. The blood-vessels and nerves are distributed amongst these tissues.
1. *The skin.*—The skin of the lumbar region is remarkable for its extreme thickness, and want of sensibility and mobility, being firmly fixed to the spines of the vertebrae.
2. *The cellular tissue.*—The cellular tissue consists of two laminae, a superficial and a deep, the former very adherent to the skin, whilst the deeper is strengthened by several processes, derived from the aponeurotic layer.
3. *The lumbar aponeurosis.*—The lumbar aponeurosis, the strongest in the whole body, deter-

mines in a great measure the form of the region. It is attached firmly to the spinous process of the lumbar vertebrae, and its anterior surface gives origin to, and binds down the erector spinae muscles. The aponeurosis of the transversalis is here divisible into three vertical laminae, namely, the posterior, which assists in the formation of the lumbar aponeurosis; the middle lamina, attached to the tips of the transverse processes of the lumbar vertebrae, and forming with the preceding a sheath for the erector spinae; and the anterior, attached to the bases of the transverse processes of the vertebrae, and forming, with the middle lamina, the sheath of the quadratus lumborum. The aponeurosis is limited by the posterior border of the external oblique muscle.

4. *The musculo-aponeurotic layer*.—The musculo-aponeurotic layer consists, on either side of the spinal line, of the mass of the erector spinae muscle and the transversospinales internal to and below it; whilst between these muscles are the branches of the lumbar vessels and nerves. Beneath these lie the transverse processes of the lumbar vertebrae, the inter-transversales muscles, the laminae of the vertebrae, with the ligamenta subflava; and, in a plane anterior, the quadrati lumborum, and ilio-lumbar ligaments. The psoas muscle enters the lumbar region.

5. *The bones*.—These consist of the lumbar vertebrae, with the inter-vertebral discs and ligaments, enclosing the cauda equina with its investments.

6. *Visceral layer*.—In front of the bones lie the pillars of the diaphragm; the inferior vena cava to the left, and the aorta to the right; on either side, the chain of the sympathetic, the lumbar glands, and the receptaculum chyl, and the commencement of the thoracic duct; and the commencement of the azygos major vein.

In front of the quadratus is a space occupied in its superior third by the kidney, and its lower two-thirds by the colon. About half the kidney lies in this space, of which the right is rather the lower of the two. The right colon is entirely enclosed in the peritoneum, whilst the left has only a partial investment of that membrane. The kidney lies external to the psoas, and upon the quadratus, corresponding with the outer side of the sacro-lumbar muscular mass. Certain anomalies in the relation of the kidneys are sometimes met with; they occasionally descend into the iliac fossa, or they may float, owing to extreme length of the blood-vessels, which penetrate the hilum, and may then be felt loosely situated amongst the other abdominal viscera. On the psoas lie—the ureter internally; obliquely the spermatic or ovarian vessels, and the sympathetic; and externally the genito-crural nerve.

Blood-vessels.—The arteries which perforate and supply this region are the lumbar arteries. The veins correspond with the arteries; they anastomose, however, with the renal veins.

Nerves.—The nerves of the region are derived from the lumbar plexus, formed by the five lumbar nerves and last dorsal; whilst the sympathetic system is derived from the solar, renal, hypogastric, and lombo-aortic plexuses.

PATHOLOGICAL AND CLINICAL RELATIONS.—The lumbar region is of great surgical importance,

from the relation to its anterior aspect of certain abdominal viscera; from the numerous fascia which enter into its formation, and their relation to abscesses, growths, and bloody or urinary effusions; and from the fact that the operations of colotomy, nephrotomy, nephrectomy, and the opening of perinephritic abscesses are performed within its boundaries. Spina bifida has a great predilection for this region. Penetrating wounds in the lumbar region are liable to involve the cauda equina, owing to the wide separation which exists between the laminae of the lumbar vertebrae. With regard to abscesses, connected with caries of the lumbar vertebrae, their situation is generally determined by their origin. When the posterior portion of the bodies or spines are affected, the pus is conducted backwards, being confined by the fascia lumborum. If the transverse processes or the anterior portion of the bones be the seat of disease, the pus will point anteriorly on the abdominal wall, being either bound down by the fascia transversalis, or conducted forwards between the abdominal muscles, in which case the pointing always takes place *above* Poupart's ligament. Renal or perinephritic abscesses often point at the border of the quadratus lumborum muscle, and may there be opened. Lumbar hernia protrudes at the so-called 'triangle of Petit.' The operations practised in the lumbar region are lumbar colotomy, nephrotomy, and nephrectomy. Of lumbar colotomy there are several modifications, but it is generally performed in the descending colon, which is usually uncovered by peritoneum posteriorly.

Other pathological and clinical relations of this region, which have many points in common with those of the iliac region, are referred to under that heading.

EDWARD BILLANT.

LUMBRICIOUS.—By many practitioners this term is still employed to designate the large round-worm (*Ascaris lumbricoides*). The title is entirely a misnomer, having originated with Tyson (*Phil. Trans.* 1683) who called the common species *Lumbricus teres hominis*. All the larger round-worms infesting man and animals are apt to be called lumbricoids. Notwithstanding their general resemblance to ordinary earth worms, their organisation is totally different. Occasionally, in practice, patients seek to deceive the medical attendant, by placing one or more earth-worms in the night-stool or chamber-pot. Quite recently the writer encountered an instance where a large garden lothworm (*L. terrestris*), about a foot in length, had been carefully selected for this purpose. The practitioner should not only be familiar with the differences of character presented by true and false worms of this kind, but should bear in mind that earth-worms cannot live in the human bladder and intestines. See ASCARIDES; and ROUND-WORMS.

T. S. CONNOLLY.

LUNACY, Law of.—The medical practitioner is frequently required to perform duties in connexion with lunacy, the satisfactory discharge of which requires that he should have some acquaintance with the legal enactments by which they are regulated. The statutes differ slightly in the three divisions of the kingdom. It will therefore be necessary, after describing what is

required under the law in England, to show where its requirements differ from those which exist in Scotland and Ireland. The details to be given here will only include what is necessary for the information of the general practitioner. Anyone who intends to devote himself specially to the treatment of the insane, or to receive one or more persons of unsound mind into his house, must comply with regulations which we cannot here set forth, but which are fully described in works upon the subject. When a person living in his own home is under treatment for insanity, the medical attendant is justified by the common law, in adopting any measures of restraint which may be necessary for safety or the proper treatment of the malady. This has been decided by the courts of law in recent cases. If, however, it is proposed to place the patient in an asylum, or to remove him to the charge of any person who is to derive profit either directly or indirectly from the proceeding, it is necessary that certain forms should be carefully observed.

In the case of a Chancery Lunatic, an order by the 'Committee of the Person,' having annexed to it an office copy of the appointment of the Committee, is sufficient authority for the reception of the lunatic either into an asylum or a private house. In the case of other private patients, it is necessary to have what is called an 'order' and two medical certificates, as in the annexed form.¹ The order may be signed by anyone having a reasonable right to interfere, provided he is neither of the medical men signing the

certificates, nor father, son, brother, partner, or assistant to either of them, nor professionally or pecuniarily connected, or to be connected in any way, with the person under whose charge the patient is to be placed. The person signing the order must have seen the patient within a month of the date of the order, and the order continues available for one month from the day of its date.

The medical certificates must be signed by registered practitioners in actual practice in England. They must have no interest, directly or indirectly, in the patient, in the establishment or house to which he is to be sent, or in his subsequent treatment; and they must not be in partnership with one another, nor otherwise professionally connected. A certificate when granted remains valid for seven days from the date of examination. The necessary form is here given. The words in italics describe a supposititious case, and are introduced merely to illustrate the manner in which the blanks must be filled up.

This document may be altogether in writing; but it is both desirable and convenient for all concerned that the regular printed forms should be used.¹

Great care must be taken to have every detail of these documents complete and accurate, for it frequently happens that what may appear to many a trifling error renders a certificate invalid, and thus entails much inconvenience and sometimes distress. The foot notes attached to the certificate will be found sufficient guides in the more important details, but the following hints will also be found useful:—1. The medical qualification must be given in full, 2. The house at which the examination was made must be accurately named, giving the name of the street, if there be any, and the number of the house; 3. The residence of the patient must be described with similar precision; and 4. The name of the person must be given, from whom the 'other facts' are obtained. The opinions at which the medical man must arrive before signing a certificate are two, and they are quite distinct. He has first to determine whether the patient is of unsound mind, and next whether it would be proper to place him under restraint. The determination that a person is insane does not necessarily imply that it is proper to place him under restraint. In stating 'the facts upon which the certificates are founded it must be borne in mind that they must be such as will appear to the Commissioners in Lunacy to be sufficient evidence of insanity, and great care must be taken to state them both intelligibly and accurately. There must be sufficient in the facts observed by the medical man himself to justify the opinion to which he certifies, the facts communicated by others being only accepted in corroboration of it; these may indeed be altogether omitted without invalidating the document. On this point the Commissioners have laid it down that the Legislature has been careful to guard against the facts communicated by others exercising

1 MEDICAL CERTIFICATE.

Sched. (A.) No. 2, Sects. 4, 5, 8, 10, 11, 12, 13.

I, the undersigned, *William Harvey*, being a (a) *Member of the Royal College of Physicians of London* and being in actual practice as a (b) *Physician*, hereby certify, that 1, on the third day of *March* 1878 at (c) *number 8 Kent Street, Norwich*, in the county of *Norfolk*, separately from any other Medical practitioner personally examined *Edward Jarvis* of (d) *number 8, Kent Street, Norwich*, *Grocer*, and that the said *Edward Jarvis* is a (e) *person of unsound mind* and a proper person to be taken charge of and detained under Care and Treatment, and that I have formed this opinion upon the following grounds; viz.:

1. Facts indicating Insanity observed by myself (f) *He states that his daughter, who has lived in his house for years, is a person unknown to him, who has been placed in the house as a spy, and made to look like his daughter. He also states that he believes Parliament intends to ruin him*

2. Other facts (if any) indicating Insanity communicated to me by others (g) *His daughter, Mary Harris, informs me that he has been sleepless and restless and much depressed in mind for the last week, and that he has on that account been unable to attend to his business.*

Signed, Name, *William Harvey*
Place of abode, *21, Chapel Street, Norwich.*

Dated this third day of March One Thousand Eight Hundred and Eighty.

(a) Here set forth the qualification entitling the person certifying to practice as a physician, surgeon, or apothecary, for example:—Fellow of the Royal College of Physicians of London, Member of the Royal College of Surgeons of England, Licentiate of the Apothecaries' Society, or as the case may be.

(b) Physician, surgeon, or apothecary, as the case may be.

(c) Here insert the street and number of the house (if any) or other like particulars.

(d) Name, residence and profession, or occupation (if any) of the patient.

(e) Lunatic, or an idiot, or a person of unsound mind.

(f) Here state the facts.

(g) Here state the information, and from whom.

¹ These forms can be obtained at the law-stationers. As they are frequently wanted with the least possible delay, we mention the names of Messrs. Shaw and Sons, Fetter Lane, and of Messrs. Knight and Co., 80 Fleet Street, as firms in the habit of supplying them.

unlike influence upon the mind of the medical man in granting his certificate, 'by requiring that this certificate shall be directly deducible from examination on a particular day and at a specified place, and that the opinion expressed therein as having been formed on such particular day shall be set forth as the result of his having observed at that time in the person under examination some specific fact indicating insanity' in the statement of the facts observed, it is therefore necessary that at least one such fact or combination of facts should be mentioned as could not be affirmed of a person of sound mind. A frequent error is the stating of facts in such an imperfect manner that though they may have been real indications of insanity as observed, the manner in which they are recorded makes them appear insufficient. It is sometimes stated, for example, that a patient 'believes himself to be possessed of great wealth,' but it is necessary that we should also state whether this is or is not a well-founded belief. And it is not infrequent to find this necessary adjunct absent from the statement. One actual statement of facts, for instance, was 'his appearance, manner, mode of speaking, as well as his conduct,' a detail of circumstances which had probably proved conclusively enough to the writer that the patient was insane, but which afforded no substantial information to those who merely read the statement. When the case is urgent, and it is found impracticable to obtain certificates from two medical men, the patient may be received into the asylum or house upon a single certificate. But this entails the necessity of obtaining two additional certificates from other medical men within three clear days after the reception of the patient.

A private patient may be discharged from the asylum or house in which he has been detained, on the written authority of the person who signed the order for his admission. If a patient should die while under detention it is necessary to give notice of the death to the Coroner and to the Commissioners in Lunacy.

In the case of pauper lunatics the procedure is somewhat different from what is required for private patients. Anyone aware of the existence of an insane pauper in a parish, ought, if the case is a proper one for asylum treatment, to give notice to the relieving officer or the overseer. When a district medical officer under the poor law becomes aware of such a circumstance it becomes his statutory duty to give this notice in writing within three days after obtaining such knowledge. The relieving officer or overseer may then place the patient in an asylum upon one medical certificate, accompanied either by the order of a justice of the peace, or by an order signed conjointly by himself and an officiating clergyman of the parish.

In order to place a patient in an asylum in Scotland, a petition accompanied by a statement and two medical certificates has to be presented to the sheriff.¹ In the case of a private patient the person signing the petition must state the degree of kinship or other relation in which he

stands to the patient. In the case of a pauper the petition must be signed by the inspector of the poor. In either case, if there be reasonable ground for so doing, the patient may be placed in the asylum on what is called a 'certificate of emergency,' signed by one medical man. If, however, the order of the sheriff is not obtained within three days thereafter, the patient must be discharged. In the case of a patient placed for profit in a private house in Scotland, the fact must be reported to the General Board of Lunacy for Scotland, and the sanction of the Board obtained.

The procedure required for placing a patient in an asylum in Ireland is generally similar to what is required in England. For admission to a private asylum, an order and two medical certificates must be filled up and signed, subject to regulations resembling those already described as enforced in England, but the facts indicating insanity do not require to be stated in the certificates. Pauper patients are placed in district asylums, and are admitted to these institutions on application being made at the asylum of the district in which the patient resides. The necessary form is obtained at the asylum. It consists of (1) a declaration to be made before a magistrate, that the patient is insane and destitute, and has no friend able or willing to pay for his board in an asylum; and to this is annexed a statement descriptive of the patient; (2), a certificate by a magistrate, and a clergyman or poor law guardian, in corroboration of the declaration; and (3), a medical certificate of insanity. When these forms have been filled up, it is necessary to wait until it is notified to some of the friends of the lunatic that there is room for him at the asylum. The procedure specially designed for the committal of dangerous lunatics is, however, frequently adopted in placing paupers in asylums. As this necessitates the lodgment of the patient in an ordinary prison, it is evidently a course which ought to be avoided, and which the medical practitioner ought specially to discourage. According to this procedure the patient requires to be apprehended by the police, and brought before two justices of the peace. They call to their aid the medical officer of the Dispensary District, and either discharge the patient or order his removal to the asylum. Patients who are not destitute, but whose friends are unable to pay the rates of board charged in private asylums, are received into district asylums at low rates, upon application being made at the asylum in a similar manner to that already described for paupers. The chief difference between the two forms is that in the case of patients not destitute, the medical certificate requires to be signed by two medical men instead of only by one.

JOHN SIBBALD.

LUNATIO (*luna*, the moon).—**STROM.**: *Fr. Lunatique*, *Ger. Mondschitzig*.—A designation given to persons suffering from mental disorder, because such subjects were formerly believed to be peculiarly affected by lunar influences. The term is used popularly as synonymous with insane. In medical literature it is seldom employed, but the legal relations of the word are important. The adjective *lunatic* is also used

¹ The regular printed forms for Scotland may be obtained from Messrs. T. and A. Constable, 11 Thistle Street, Edinburgh.

to signify that the object with which it is associated is connected with insanity, as *lunatic asylum*. See INSANITY.

LUNGS, Diseases of.—**SYNON.**: Fr. *Maladies du Poupon*; Ger. *Krankheiten der Lungen*. Under this title there will be described in the following pages, with certain exceptions, the various morbid conditions which affect the pulmonary organs. Pulmonary phthisis is so common a disease, so complex and variable in its pathology, and so closely associated in its etiology and symptoms with the entire organism, that it will be most conveniently described apart from the other diseases of the lungs (see PHTHISIS). Certain other diseases which involve the lungs, if not the lung-tissue proper, and which in some nosological systems are described as pulmonary diseases—namely, asthma, diseases of the bronchi, and diseases of the pleura, will also be found described apart from the present connection, and under their several headings. Again, disorders of respiration, such as dyspnoea, orthopnoea, and ‘Cheyne-Stokes respiration,’ although frequently associated with diseases of the lungs, are in other instances referable to some morbid condition of other parts, such as the blood, the heart and circulation, or the nervous apparatus of breathing, and they will therefore be discussed in a distinct article (see RESPIRATION, Disorders of). The more important special clinical phenomena of disease of the lungs—namely, cough, expectoration, hæmoptysis, and the various physical signs, also demand more detailed and complete consideration than can be devoted to them in connection with the various pathological conditions to which they are due. See COUGH; EXPECTORATION; HÆMOPTYSIS; and PHYSICAL EXAMINATION.

After the separation of these subjects from that of diseases of the lungs, there remain for consideration under this head a large number of morbid conditions, which rank of the very first importance in practical medicine, and which will now be enumerated. The morbid processes which affect the lungs may be readily divided into two great groups—namely, first, those which are not essentially different from similar processes in other parts of the body; and, secondly, those which are quite peculiar to these organs.

First, with respect to the former group, the lungs, like the other great viscera, may present any of the ordinary morbid conditions, which affect either entire organs, or the several tissues of which they are composed. Thus the lungs may be the subject of various injuries, leading to *perforation* or *rupture*, and may present certain *malformations* and *misplacements*. They may undergo such alterations of nutrition as end in *atrophy*, *hypertrophy*, or certain *degenerations*. Disturbances of circulation give rise to well-defined pathological conditions, such as *anæmia*, *congestion*, *hyperæmia*, *apoplexy*, *embolism*, *infarction*, *œdema*, and *hæmorrhage*. The inflammatory process leads to a greater variety of pathological changes in the lungs than in perhaps any other organ, and which are known as *interstitial*, *croupous*, and *chronic pneumonitis*, *abscess*, *abscess*, *gangrene*, and some forms of *phthisis*. *Morbid growths* of all kinds, including

malignant disease, may involve the lungs, whether primarily or secondarily. *Syphilis*, besides actually involving the lungs, occasionally determines or modifies the occurrence of other pathological processes within them. Various *parasites*, especially *hydatids*, are occasionally tenants of the pulmonary organs.

Secondly, the morbid conditions which are *peculiar* to the lungs are such as depend upon their special structure, relations, and functions. Thus the relation between the pulmonary tissue and the pressure within and around the lungs may be so disturbed as to lead, on the one hand to *collapse* or *compression*, or on the other hand to *emphysema*. Their communication with the atmosphere, and the constant interchange that is going on between the contents of the lungs and the external air, have an important influence upon the origin, distribution, progress, and treatment of many of the diseases which affect them, whilst the length and complexity of the respiratory passages and their liability to disease, lead to many disturbances of the pressure, the circulation, and the nutrition within the lungs, and thus to collapse, hyperæmia, inflammation, and even destructive disease. The relation of the lungs to the circulation has an equally important influence upon them from a pathological point of view. Constituting as they do the channel of communication between the right and the left sides of the heart, the pulmonary vessels are involved in all the disturbances which affect the cardiac circulation, whether due to actual disease of the valves or of the walls, or to simple functional derangement of that organ. Congestion, œdema, embolism, infarction, hæmorrhage, and some forms of inflammation of the lungs, are the ordinary results of such circulatory disturbances of a temporary kind; and when it is more protracted, *brown induration*, as well as diseases of the bronchi and pleura, are likely to result.

Such are the principal conditions which determine and influence diseases of the lungs; and we shall here enumerate these in the alphabetical order in which they will be found referred to in the following pages:—1. Abscess. 2. Albuminoid Disease. 3. Anæmia. 4. Apoplexy. 5. Atrophy. 6. Brown Induration. 7. Cancer. 8. Cirrhosis. 9. Collapse. 10. Compression. 11. Congestion. 12. Consumption. 13. Degenerations. 14. Embolism. 15. Emphysema. 16. Gangrene. 17. Hæmorrhage. 18. Hydatids. 19. Hyperæmia. 20. Hypertrophy. 21. Induration. 22. Infarction. 23. Infiltrations. 24. Inflammation—Croupous, Secondary, Catarrhal, and Chronic. 25. Inflation. 26. Malformations. 27. Malignant Diseases. 28. Malpositions. 29. Morbid Growths. 30. Œdema. 31. Perforation. 32. Rupture. 33. Syphilitic Disease; and 34. Tuberculosis.

LUNGS, Abscess of.—**SYNON.**: Fr. *Abcès du Poupon*; Ger. *Lungenabscess*.

DEFINITION.—Circumscribed suppuration of the pulmonary tissue.

ÆTIOLOGY AND PATHOLOGY.—An acute primary inflammation of the lungs may occasionally lead to the formation of abscess. Much more commonly, however, pulmonary abscesses

are the result of secondary or infective inflammations, and they are then, for the most part, associated with pyæmia.

Of acute primary inflammations of the lung, as causes of abscess, we have to consider those due to mechanical injuries, and those associated with acute pneumonia and with gangrene. With regard to the former it is only necessary to remark that mechanical injuries, as fractured ribs, penetrating wounds of the thorax, the lodgment of foreign bodies, &c., may cause suppuration, and so occasionally lead to the formation of abscess. That acute pneumonia may, in rare cases, terminate in abscess of the lung, has already been stated. Such a result appears to be favoured by a bad constitution, and by any circumstances which tend to impair the general health, either before or during the disease. The abscess is more common in the upper than in the lower lobes. Lastly, circumscribed gangrene of the lung occasionally terminates in abscess. This takes place by the evacuation of the necrotic tissue through the bronchi, and the formation of a pyogenic membrane from the walls of the cavity, which generates pus. The cavity may ultimately close by granulation and cicatrization. Abscesses of primary origin are usually single.

Secondary or infective abscesses of the lung owe their origin to the dissemination of infective substances, derived from some focus of primary inflammation, by means of the blood-vessels or lymphatics. They are usually due to a general pyæmic process; and consequently the blood-vessels are the channels by means of which the infective substances are conveyed to the lungs. These substances are sometimes sufficiently large to block the pulmonary vessels, the formation of the abscess being preceded by a process of hæmorrhagic infarction. In other cases the suppuration occurs without any evidence of such infarction taking place. These abscesses are almost invariably multiple. They vary in size from a pin's head to a walnut, and are usually most abundant near the surface. They are commonly surrounded by a thin zone of dark red consolidation; and when adjacent to the pleura, this membrane over them is always inflamed.

SYMPTOMS AND PHYSICAL SIGNS.—The formation of abscess in the lung is rarely attended by any marked clinical phenomena, the symptoms of the disease, in the course of which the localized suppuration takes place being, for the most part, but little modified by its occurrence.

When acute pneumonia terminates in abscess, either the rapid fall of the temperature which constitutes crisis does not occur, or, what is more common, its occurrence is followed by pyrexia of an irregular type. The physical signs of consolidation also persist, and there is usually great prostration. Sometimes, owing to the opening of the abscess into a bronchus, pus is coughed up; and then, if the communication with the bronchus remain free, signs of cavity are discoverable. Before such partial evacuation of its contents, the detection of the abscess by physical examination is usually impossible. The expectoration of sputa containing large quantities of pus, and often a little blood, may continue for some weeks; the signs of prostration

may gradually increase; and death may ensue in the course of from two to three months, and often earlier. Partial or complete recovery may, however, take place, the cavity becoming quiescent and secreting only small quantities of pus; and complete cicatrization may ultimately occur. In exceptional cases the abscess opens into the pleural cavity.

Abscesses of the lungs occurring in the course of pyæmia rarely give rise to any special symptoms or physical signs. They are usually much smaller than primary abscesses; and death commonly ensues before any of them have attained sufficient magnitude to influence the general phenomena of the disease.

DIAGNOSIS.—The diagnosis of abscess, occurring in the course of pneumonia, rests mainly upon the persistence and characters of the pyrexia; upon the physical signs of excavation supervening on those of pulmonary consolidation; and upon the expectoration of sputa containing pus. Pyæmic abscesses rarely admit of diagnosis. Their existence may be suspected if, in cases of pyæmia, pleural friction-sounds are audible over different portions of the chest.

PROGNOSIS.—Abscess resulting from pneumonia very commonly proves fatal in from one to three months; it may, however, as already stated, ultimately terminate in partial or even complete recovery. The development of abscesses in the lungs in the course of pyæmia does not appear to influence the general prognosis.

TREATMENT.—Abscesses of the lungs rarely admit of any special treatment. Their occurrence, however, indicates the importance of doing all that is possible to maintain the strength of the patient. T. HENRY GREEN.

LUNGS, Albuminoid Disease of.—In advanced cases of albuminoid disease, the lung-tissues may present more or less of this morbid change; but it is of no practical importance, for it does not give rise to any evident symptoms, nor does it have any specially injurious effect upon the patient.

LUNGS, Anæmia of.—SYNON.: *Fr. Anémie du poumon*; *Ger. Lungenanämie*.

DEFINITION.—A deficiency of blood in the lungs.

Anæmia of the lung may be *general* or *local*.

ÆTIOLOGY.—Besides hæmorrhage and the other causes of general bloodlessness, there are certain local causes which produce anæmia of the lung. In senile atrophy, and in pulmonary vascular emphysema, anæmia is associated with destruction of capillaries. Local or partial anæmia of the lung is the immediate result of embolism of the branches of the pulmonary artery. It rarely happens that the main vessel is entirely obstructed by an embolus; but it, or more commonly one of its main divisions, may be compressed or obliterated by the invasion of a malignant growth or aneurism. Anæmia of a branch of the pulmonary artery within the lung usually causes anæmia of the portion to which the vessel is distributed.

ANATOMICAL CHARACTERS.—In extreme anæmia, as after death from hæmorrhage, the lungs and the bronchial mucous membrane and ex-

needingly pale from absence of blood.¹ They are of course lighter in weight than natural, but in other respects unchanged. In the general disease known as anæmia, the lung partakes with other organs of the general deficiency of red blood, but in this condition, it being not so much in bulk as in quality that the blood is deficient, the lungs are of normal weight, but paler and more moist than natural, sometimes slightly oedematous.

EFFECTS.—The consequences of pulmonary anæmia, when long-continued, are atrophy of its texture, as in senile atrophy and vesicular emphysema, and in local deficiency of blood from partial obstruction of a large branch of the pulmonary artery. In complete obstruction of vessels from embolism, death and sloughing of the deprived area of lung is the consequence. The sudden arrest of circulation through a limited portion of the lung, gives rise to stroms on the collateral circulation, the result of which is often hæmorrhage.

SYMPTOMS.—The dyspnoea and palpitation observed in anæmia are traceable to the anæmic condition of the lungs, and have their rationale in the necessity for an increased diligence of respiration, to enable the diluted blood to gather sufficient oxygen for carrying on the various combustion-processes of life. The remarkable gasping and restlessness seen in cases of fatal hæmorrhage, are really the signs of asphyxia from pulmonary deprivation of blood. The symptoms of general or local pulmonary anæmia dependent upon emphysema, embolism, &c., are lost in those of the more important diseases.

TREATMENT.—There is no special treatment for pulmonary anæmia. R. DOUGLAS POWELL.

LUNGS, Apoplexy of.—A synonym for extravasation of blood into the lungs. See *Lungs, Hæmorrhage into*.

LUNGS, Atrophy of.—SNOW: Senile emphysema; Fr. *Atrophie du Poumon*; Ger. *Lungenatrophie*.

DEFINITION.—A wasting of the constituent elements of the lungs, from defective nutrition.

VARIETIES.—Atrophy of the lung may be:—(a) *general*, in which all the tissues of the whole of both lungs are wasted, as in senile atrophy; or it may be (b) *local*, in which all the tissues of a portion of the lung are wasted, as in the atrophy that results from a local diminution of blood-supply; or (c) it may be *partial*, in which some of the tissues are atrophied coincidently with increased growth of other tissues, as in some cases of so-called 'hypertrophic emphysema,' and in 'cirrhosis' of the lung.

ÆTIOLOGY.—The cause of simple atrophy of the lungs is that general failure of nutrition which is natural to advanced age. Hereditary predisposition may determine an earlier failure of nutritive change in the lungs. The strongly-marked tendency of vesicular emphysema to recur in successive generations is certainly in favour of such a tendency to premature impairment of tissue being inherited.

OVER-STRETCHING of the walls of the air-cells in emphysema, with the consequent impediment to circulation, is an important cause of subsequent atrophy in this disease. Collapse and anæmia

of lung from pressure from without, or from the pressure of a growth or aneurism upon one of the pulmonary vessels, cutting off the blood-supply, or on a large bronchus, diminishing the respiratory function, may cause atrophy of the whole or of a part of one lung.

ANATOMICAL CHARACTERS.—The appearance of an atrophied lung may be best seen in a case of natural or senile atrophy. The lung is small, light, anæmic, more or less deeply pigmented, drier in texture and less firm and resisting than natural, pitting on pressure from want of elastic resilience, and capable of being squeezed into a very small compass. The air-cells appear to be increased in size, and, at some portions, if the lung be inflated and dried, large cells may be seen, evidently resulting from the coalescence of two or more infundibula. Across such cells filaments, the remnants of small bronchi and blood-vessels, may extend. The pulmonary artery and its branches are diminished in size, and the bronchial tubes are also thinned.

Microscopical characters.—The atrophic process commences at the vascular septa, which project inwards to subdivide the infundibula, or alveolar spaces of the lung, into true air-cells, or alveoli. The process is one of simple withering and obliteration of capillaries, dependent on diminished respiratory function and blood-volume. The septa dwindle down to mere ridges upon the infundibular walls, and these walls in their turn become thinned even to perforation and coalescence of several air-spaces. Thus, without any corresponding enlargement of lung, there is an apparent enlargement of air-cells from the simplification of structure. A certain degree of fatty degeneration, affecting especially the minute vessels and the nuclear remains of the pulmonary epithelium is associated with this simple atrophy, as with all other atrophic processes.

When atrophy of the lung is associated with, or the result of, other diseases, as emphysema or forcible collapse, the process is essentially the same, but is combined in the former case with over-stretching of the air-cells, and more or less thickening of the fibrous tissues derived from the bronchial and perivascular sheaths, from repeated congestions. Thus we have a larger and heavier lung, and, in the later stages, more marked fatty degeneration of its fibrous texture.

In cases of atrophy from the long-continued pressure of fluid in the pleura, the pleura is always thickened from the original inflammation, and fibrous processes are directed inwards from it between the lobules, so as to render difficult any subsequent expansion of the lung.

In the case of atrophy from compression of the lung by fibrous growth or fluid effusion, we have again often a heavier lung from increase of fibrous tissue. It is obvious that the increase in weight must always be due to attendant, often determining, disease.

EFFECTS AND SYMPTOMS.—The consequences of the partial atrophy of lung which accompanies the 'large-lunged' emphysema of advanced middle life are very grave. Extensive obliteration of the pulmonary capillaries, without a corresponding diminution in the blood-volume, induces a stroms of circulation, a mechanical congestion, which ultimately tells back through

the right heart upon the whole venous system. The damaged elasticity of the lung impairs the mechanism, as the atrophy of the alveoli impairs the function of respiration. In senile emphysema, however, the lung-atrophy being but a part of a general atrophy of all the tissues and of the blood, causes no discomfort, provided no extra efforts attempted and no bronchitis supervene. Local atrophy of the lung has its symptoms moral in those of the predominant disease.

Physical signs.—In senile atrophy of the lungs the chest-capacity is diminished in all directions to accommodate the small lungs. The lower ribs are approximated and their obliquity greatly increased, the upper intercostal spaces are depressed. The chest-movements are very limited. The percussion resonance is generally increased over the chest, except over the precordial region, which is less covered by lung than natural. The respiratory murmurs are simply enfeebled, not altered, unless there be some bronchitis present. It has been said that there may be some effusion into the pleura in atrophy of the lung, to fill up the space vacated by the shrunken organ. The mechanism of such an effusion is, however, quite inconceivable.

Complications.—There are no complications necessarily incident to senile atrophy of the lung. Bronchitis not uncommonly, however, supervenes, and proves fatal to the patient.

Treatment.—The treatment of senile atrophy of the lungs simply consists in shielding the aged person from the causes of bronchitis.

R. DOUGLAS POWELL.

LUNGS, Brown Induration of.—The condition recognised by this name by Virchow and Laennec, is one which is sometimes observed after prolonged congestion of the lungs, particularly that which results from disease connected with the mitral orifice. The morbid change consists mainly in excessive pigmentation, the pigment accumulating not only in the interlobular tissue, but also in the alveoli and minute bronchi, where it is enclosed in enlarged epithelial and granular cells. At the same time the capillaries are dilated, the interstitial tissue is increased, and probably the alveolar walls are thickened. The pigment is granular, and of a yellowish colour, it is derived from the blood, and seems to be of the nature of hæmatoidin. It may become brownish, reddish, or even black, and ultimately may be found free. The extent and degree of brown induration vary much in different cases. When the change is marked, the lungs are enlarged, heavy, firm, incompressible, and inelastic, not collapsing on exposure. They present various tints, from yellowish to reddish-brown. This alteration in colour is also evident on section, and red spots are often seen, shading into black, while a brownish fluid may be expressed. Brown induration is associated with congestion of other parts of the lungs, and often with infarctions. It cannot be clinically recognised apart from these conditions, unless the affected organs should present physical signs of consolidation in cases of known pulmonary congestion from mitral disease. No special treatment is called for.

FREDERICK T. ROBERTS.*

LUNGS, Cancer of.—See *LUNGS, Malignant Disease of.*

LUNGS, Cirrhosis of.—A synonym for chronic pneumonia. See *LUNGS, Inflammation of.*

LUNGS, Collapse of.—SYNON.: *Apneumotorix*; Fr. *Affaissement pulmonaire*; Ger. *Leugencollapsus*.

Definition.—Simple diminution in size of the whole or of a part of a lung, with reduction of the volume of the contained air, and caused by interference with its free entrance in inspiration.

Ætiology.—The causes of collapse of the lung are either *intrinsic* or *extrinsic*; and frequently the two classes of causes are combined. The *intrinsic* causes present actual obstruction of the respiratory passages, and include all diseases of the larynx, trachea, and bronchi, attended with inspiratory dyspnoea, whether due to the pressure of external tumours, to affections of the passages themselves, or to the presence of inflammatory products, blood, and foreign bodies within them. To this class of causes belongs the collapse of the lung which is apt to follow infantile bronchitis, when the tubes become obstructed, and there is no power to expectorate. All causes that interfere with respiratory efficiency favour the occurrence of the condition named. A plug of mucus may be drawn, in inspiration, deeper and deeper into the bronchial tubes, which it obstructs, and acting like a 'ball plug,' allows the expulsion of air in expiration, but interferes with inspiration; the air not being replaced, apneumotorix is developed; and as there is no air behind the plug of mucus, cough is powerless to expel it. In children, bronchial inflammation is exceedingly common, and the smaller tubes being proportionately smaller in the child than in the adult, the danger of collapse is increased. When children under five years of age die of bronchitis and allied affections, apneumotorix is almost invariably present, and 25 percent of the total mortality of infants may be safely set down to this cause. Partial collapse of the lung from pressure on the respiratory passages will be found described in the article *MEDIASTINUM, Diseases of*. The *extrinsic* causes of pulmonary collapse are certain conditions of the walls of the chest, which diminish the force of the inspiratory act, such as paralysis or debility of the inspiratory muscles, and softness of their bony attachments. Muscular paralysis is seen in injuries to the cord. Debility of the respiratory muscles may often be observed before death. Collapse of the lung is sometimes, although rarely, met with in adult life, when great prostration occurs in the course of fever, and respiration is impeded by pulmonary congestion. Associated as it is with softness and weakness of the ribs, rickets is one of the most frequent causes of collapse of the lungs. The action of the inspiratory muscles may be still further interfered with by abdominal distension, or by the binding up of the abdomen of the infant with tight bandages. The danger of collapse is lessened when the ribs have gained firmness and fixity, and when, raised by the respiratory muscles, the thoracic cavity is enlarged, and the lungs are consequently expanded.

ANATOMICAL CHARACTERS.—The whole of one lung or of one lobe may be affected, but a lobule or a part only of the lung is usually involved, the affected lobules being abruptly separated from those adjoining. As a rule several patches of collapse occur in each lung, having a darker colour and more depressed surface than the healthy parts. The lower margins of the left lower lobe are most frequently affected. The collapsed portions of lung are similar to the liver in consistence; they resist pressure, are non-crepitant, are smooth on section, and sink in water. The bronchi are filled with mucous fluid; there is an entire absence of air in the collapsed parts. On inflation the affected portion assumes a natural appearance, unless considerable congestion exists; whereas in pneumonia inflation cannot restore the lung to its natural appearance. In pneumonia pleurisy is rarely absent; but in collapse, uncomplicated with diathetic disease, the pleura is invariably healthy.

SYMPTOMS.—The symptoms of collapse of the lung vary greatly with the cause, rapidity, and extent of the morbid condition. In severe cases, for example, in the collapse that follows bronchitis in very young subjects, the symptoms are peculiar. There is great prostration, debility, restlessness, and sleeplessness. The temperature falls; the surface becomes cold, blue, or dusky; the eyes become shrunken, and the pulse is quick and small. There is a constant feeble whining cry. Respiration is very quick and shallow, as high as 70 to 80 or even 100 per minute. The rhythm is changed, the interval being between inspiration and expiration, instead of after expiration. There is no pain as in pleurisy. The cough is constant and impotent; is often followed by a cry of impatience; and differs much from the suffocative cough of bronchitis.

On examining the chest, the lower part is found retracted and diminished in diameter. The intercostal spaces sink in inspiration, and move outwards slightly in expiration. When the collapse is extensive the percussion is dull and resistant, unless the affected lobules are interspersed among the healthy ones. The respiratory murmur is lost over the affected parts, though conducted breath-sounds, of a bronchial character, and rhonchi are generally audible almost universally. In the simpler cases of collapse of the lungs, such as occur in pertussis during the severe fits of coughing, some of these symptoms and signs may be suddenly developed, and again speedily disappear.

DIAGNOSIS.—Apneumonia may be distinguished from croupous pneumonia by the comparative rarity of the latter disease in infancy; and by absence of the great heat of skin, and of fine expiration on auscultation. From extensive military tuberculosis it is diagnosed by the absence of advancing symptoms of constitutional disorder, though the two conditions may co-exist. In pleurisy the dulness on percussion, and the absence of respiratory sounds at the base, are much more marked than in apneumonia. Congestive collapse or atelectasis is a condition which has to be diagnosed from infantile collapse or apneumonia. Readily separable by symptoms, these two conditions may be indistinguishable by

physical signs. In atelectasis the lung retains, in whole or in part, its fetal condition, nature having failed to establish respiration and fit the child for its new mode of existence. In apneumonia the once permeable lungs cease to admit air, and thus death from apnoea occurs without any apparent structural change being discoverable, save that the respiratory organs bear the appearance of fetal, unexpanded lungs.

PROGNOSIS.—The prognosis in collapse of the lung is favourable if the affection is recent, and the child healthy, with fair muscular power, and under favourable hygienic conditions. On the contrary, the disease is generally fatal if it involve a considerable extent of lung, especially if it supervene on atelectasis. Death usually occurs from slow asphyxia, the effect being the same as if the size of the lung were reduced by the removal of the affected parts. As much as half of the entire lungs has been found involved, thus fully accounting for the quickened respiration, the distress, and the dyspnoea, and for the bloodlessness and extreme pallor, with cold, blue extremities. The fatality of whooping-cough in infants is mainly due to the ready collapse of the lungs, specially when the child is badly nourished and breathing impure air. The natural course of the disease is from bad to worse; more lung is involved each day, and death occurs after two or three weeks from slow asphyxia. If collapse follows acute bronchitis death often ensues rapidly, but if recovery takes place the lungs are slow to regain activity, and the seeds of future mischief remain. After an attack of pneumonia complete absence of breath-sounds may exist for a time, and then suddenly—after a blow, shock, or violent cough—air enters the collapsed portion of lung, and the respiratory sounds assume a normal character.

TREATMENT.—When this affection was looked upon as a form of pneumonia it was treated by depletion. Now that we realise that it is not of an inflammatory character, our object must be not to lower vitality but to diminish excessive secretion. Slight counter-irritation, by means of stimulating embrocations, is useful. An emetic of ipecacuanha will help to remove accumulation if the patient is not too weak. Expectoration may be promoted by small doses of the same drug. When the lungs are extensively involved, vital power must be kept up by the help of ammonia, steel, phosphates of iron, port wine, and beef-tea; and the food must be so designed as to be digestible by the stomach of the infant.

E. SYMES THOMPSON.

LUNGS, Compression of.—*SYNON.*: Fr. *Compression du Poumon*; Ger. *Lungencompression*.

DEFINITION.—Diminution in size of the whole or of a part of a lung, associated with reduction of the volume of the contained air, and caused by pressure on the pleural surface.

ÆTIOLOGY.—Compression of the lung may arise in the course of numerous diseases or injuries affecting the chest, the compressing influence being either gaseous, liquid, or solid.

First, the admission of air to the pleura from without, through a perforating wound, as from a sword or bayonet thrust, or from within, as by

rupture of an air-cell, or the extension of pulmonary ulceration through the pleura, produces in either case compression. If no previous pleurisy has existed the compression is complete, but if, on the other hand, long-standing pleurisy has caused adhesion, compression cannot take place, or will be but partial. Pneumothorax, arising without perforation may be due to the evolution of gas from gangrene, or to the decomposition of pleuritic fluid, or the gas may be directly secreted within the pleura, taking the place of serum absorbed after pleuritic effusion. Besides the causes named, perforation may arise from fractured ribs with pulmonary laceration, or from contusion of the lung without fracture; from ulcerative perforation of lung, either tuberculous or gangrenous, from pulmonary apoplexy, hydatids, cancer, empyema, abscess, from rupture of the lung in whooping-cough; from perforation of the lung from without, by diseased and suppurating bronchial glands opening into the pleura and bronchi; and from rupture or ulceration of the œsophagus, opening into the pleura. Of this long list, omitting the surgical causes, nine out of ten are due to phthisis.

Secondly, compression may arise from the presence of *fluid*, such as pleuritic effusion, acute or chronic; purive, non-inflammatory effusion, as in hydrothorax, or blood, as in hæmatorrhax.

Thirdly, compression of the lung by *solids* is seen in the case of various tumours of the chest, whether originating in the mediastinal structures, in the lungs, or in the thoracic parietes.

In a fourth class of cases compression of the lung is the result of the enlargement of neighbouring parts, other than the thoracic viscera, and especially of the abdomen, as in ascites, and tumours of the liver, spleen, or ovaries.

ANATOMICAL CHARACTERS.—Compression of the lung may be either general or local, complete or partial. A lung compressed by pleuritic effusion is found to be reduced in volume, non-crepitant, dense, and quite insusceptible of inflation. The blood is conglobated in the affected lobes, the clot being often decolourised and adherent to the walls of the vessels, many of which are impervious, or altogether obliterated, while the perivascular vessels and the air-cells of the adjacent parts are distended, and emphysema is produced. In other cases, the compressed lung proves to be anæmic, tough, and dry.

In cases of slow recovery from chronic empyema the lung is often found bound down and thickened, having very little normal pulmonary tissue remaining. The thoracic cavity vacated by the shrunken lung is occupied by the displaced heart, and sometimes by the extension of the sound lung across the middle line.

When perforation occurs with admission of air from the bronchi to the pleural cavity, the atmospheric pressure distends the pleura, and tends to displace the mediastinum and the other lung. The heart, too, being unsupported, is pressed against the healthy lung, and may be displaced to a very considerable extent.

SYMPTOMS AND PHYSICAL SIGNS.—The symptoms of compression of the lung vary greatly in accordance with its causes, the rapidity of onset,

and the extent and degree of compression. If pleuritic effusion be very rapid, the dyspnoea may be exceedingly urgent. After perforation of the pleura with sudden collapse of the lung, there also occur acute pain, dry cough, and painful spasms of the intercostal muscles. The pulse is frequent, feeble, and often irregular. Symptoms, more or less acute, of inflammation may follow. In other instances the symptoms are those of hydrothorax, or of intrathoracic tumour.

The physical signs of compression of the lung are chiefly those of the associated cause, such as pneumothorax, pleurisy, hydrothorax, or intrathoracic tumour; and partly certain phenomena characteristic of the physical condition of the lung itself. The latter vary considerably with the degree and extent of compression, but they may be described in general terms as follows:—Either increased clearness of the percussion sound over the area of compressed lung, with tubular or rarely even tympanitic quality, especially in children, or in extreme cases of compression complete loss of resonance; indefinite, weak, but occasionally rather blowing or tubular respiratory sound, sometimes mixed with scanty, dry, subcrepitant rhonchus; and exaggerated loudness and ringing quality of vocal resonance. A further description of these symptoms and signs will be found under the headings of the various causes of compression referred to.

DIAGNOSIS.—The diagnosis of compression of the lung is in general simply the diagnosis of the condition on which it depends.

PROGNOSIS.—The prognosis depends on the cause of the compression. Thus in pneumothorax it is unfavourable, though recovery may take place. In hydrothorax the prognosis is unfavourable, as it is usually an evidence of formidable, if not incurable, organic disease. In pleurisy, if the effusion has been rapid, met by prompt treatment, and uncomplicated with hectic, complete recovery may take place without much compression of lung or distortion of chest; but incompletely-cured pleurisy is too frequently the first incident in the history of phthisical disease. In empyema the prognosis is more favourable than in pneumothorax or hydrothorax.

TREATMENT.—Little need be said as to the treatment of lung-compression. It resolves itself into that of the intercurrent or causative diseases. Bearing in mind the injury done to the lung by compression, efforts should be made to relieve the lung before it has been irremediably bound down. The early adoption of paracentesis thoracis is the most practical means of gaining this end in pleuritic effusion. Remedies calculated to remove effusion and thus relieve the lung should be given, remembering that the more speedy the relief given to the lung the more complete will be the cure. Suitable movements of the chest might be ordered subsequently, with the view of promoting expansion of its walls and of the lung.

LUNGS, Congestion of.—See *LUNGS, Hypermia of*.

LUNGS, Consumption of.—See *PHTHISIS*.

LUNGS, Degenerations of.—See *CHANGES*

a degenerative character in connection with the lungs constitute an important element in some pulmonary diseases, or they may be the sole morbid condition present. They are of the following nature:—

1. *Albuminoid*.—This is only occasionally noticed, in marked cases of general albuminoid disease.

2. *Fibroid*.—Changes leading to a more or less fibroid condition of the pulmonary tissue are of common occurrence, but it is not always easy to determine whether they should be regarded as due to a chronic inflammatory process, or to degeneration, and pathologists differ in their views on this point. As a degeneration, the fibroid change may be considered as most important in connection with emphysema, and it is regarded by some authorities as an element of much consequence in the causation of many cases of this disease. It also follows long-continued congestion, and collapse or compression of the lung from any cause. Of course much fibroid or fibrous tissue is found in the lungs in many cases of phthisis, and in connection with pleuritic adhesions and other conditions, but this state must be looked upon mainly as of inflammatory origin. The effects of these changes are to make the lung-tissue firmer and tougher, but at the same time to diminish or destroy its elasticity, the elastic tissue being more or less displaced. Hence, if the lungs be exposed to any distending force, they cannot recover themselves properly, and the air-vesicles remain more or less permanently dilated.

3. *Fatty*.—This degeneration is also regarded by some pathologists as one of the main elements in originating many cases of emphysema of the lungs, and also as one of the actual conditions in this disease. Here, again, the lung-tissue is impaired in its elasticity and resisting power to distension, but it is not tough. Granular fat may be visible under the microscope.

4. *Pigmentary*.—The lungs become the seat of more or less pigmentation with increasing age. They are also markedly affected in certain occupations in which carbonaceous matters are inhaled. In so-called brown induration of the lungs there is an abundance of pigment.

5. *Senile*.—The lung-tissue undergoes atrophy, with more or less loss of elasticity, owing to wasting of the elastic tissue with increasing age, and even a fatty degeneration may take place. Hence, in such subjects emphysema is readily set up by causes which would have no effect on younger persons.

6. *Secondary*.—Under this head may be included those degenerative changes which take place in morbid formations in the lungs, such as inflammatory deposits, tubercle, or cancer. These belong mainly to the fatty or caseous variety of degeneration, but calcification may also occur.

LUNGS, Embolism of.—*See* LUNGS, Anæmia of; and LUNGS, Hemorrhage into.

LUNGS, Emphysema of.—*SYNON.*: *Emphysema des poumons*; *Ger. Lungenemphysem.*

Definition.—An excess of air in the lungs, resulting due to a dilated condition of the air-

sacs, or to the presence of air in the interlobular tissue.

VARIETIES.—There are two kinds of emphysema of the lungs, namely:—

A. *Vesicular Emphysema*.

B. *Interlobular Emphysema*.

A. *Vesicular Emphysema*.—Pulmonary vesicular emphysema exists in three forms, namely,

1. *partial lobular*; 2. *lobular*; and 3. *lobar*. The last form involves the whole of a lobe, or the whole of one or both lungs. The first form is rarely seen alone, but is generally associated with the second form, which is very common, and is found in connection with diseases, such as bronchitis, which are attended with violent or long-standing cough. The third form is by far the most important, and will be more especially referred to in the present article. It more frequently attacks both lungs than one, and the lower as well as the upper lobes. It is a serious malady, and sometimes destroys life at an early period. Its features are characteristic, the lung-substance has a peculiar doughy feel; pits on pressure; is wanting in healthy crepitation; and has a colour very closely resembling that of a calf's lung. It has been described as 'large-lunged vesicular emphysema.'

Ætiology.—*Determining causes and mechanism*.—With reference to the determining causes of emphysema there are two theories, namely, the inspiratory theory, and the expiratory theory. On the first view the dilatation and rupture of the air-sacs are accounted for by the over-distension of the lungs in inspiration. On the second view these changes are considered to be caused by the strain to which the lung-tissue is subjected in violent expiratory efforts, especially the act of coughing. It has been thought by others that emphysema must be looked upon as a complementary lesion, arising in consequence of the over-distension to which the healthy portions of the lungs are subjected in cases of pulmonary collapse. Without entering into any critical examination of the theories as to the mechanical causes of emphysema, it may perhaps be sufficient to say that there can be little, if any, doubt that the lobular forms of the disease are mainly produced by expiratory efforts, such as violent cough, or blowing wind instruments. They have their seat in those parts of the lungs which become most distended by such acts. With regard to the lobar form of the disease, however, this explanation of its mechanism does not suffice. In this affection the inspiratory power is that which distends the lungs. The pulmonary tissue has lost a portion of its elasticity, it yields to distension, and no longer re-acts perfectly when the distending power ceases. Further distension follows; reaction diminishes still more; until at length in some instances the lungs become greatly enlarged.

In senile cases the loss of elasticity of the chest-walls aids in preventing the pulmonary reaction.

ANATOMICAL CHARACTERS AND PATHOLOGY.—

In the early stages of emphysema there is simply a dilatation of the air-sacs; an increase in the size of the alveoli; and a diminution in the height of the alveolar walls, which yielding with the distending cavities, become partially

obliterated. As the disease progresses the air-sacs become more distended, and the walls of the alveoli sometimes completely obliterated, so that the air-sacs are quite smooth, instead of honeycombed. Then follows perforation of the *regr-sacs*—at first slight, here and there an oval opening being discoverable, afterwards the openings become more numerous and larger. The subsequent progress of the disease is attended with further distension of the air-sacs, and rupture of the fibres of their walls. The openings thus caused coalesce, until at length the walls are simply represented by membranous shreds, and even large vesicles may form. These changes, varying in degree, characterize all the forms of emphysema. In the lobular form, however, perforation takes place to a much greater extent *quoad* the amount of dilatation, than in the lobular or partial lobular form.

The emphysematous lung is anæmic, its blood-vessels become widely separated, and often ruptured and atrophied. The bronchial tubes are sometimes dilated, especially in old-standing cases, and in these there is frequently found an increased development of the circular muscular fibres.

The pathology of emphysema involves some important points for consideration. The great question is whether there is any degeneration of tissue preceding or attending the affection. When the disease is partial, and has followed or is attended by bronchitis, or some other affection in which there has been violent or long-standing cough, the emphysema may be the result of mechanical violence, without pre-existing degeneration of the lung-tissue. When, however, it is of the lobular form, degeneration is probably the primary step in the affection. The facts which tend to confirm this view are—(1) the insidious manner in which the disease sometimes comes on, and the development which it attains, without any previous history of violent or long-standing cough, (2) the frequency with which it attacks the whole of both lungs, and (3) its hereditary character. The exact nature of the degeneration has not been satisfactorily made out. Fatty matter has been found in a few instances, but not in all cases. The degeneration is probably one primarily involving the elastic fibres and other structures of the walls of the air-sacs. Whatever be the nature of the degeneration, there can be no doubt that lobular emphysema is a malady resulting from some form of mal-nutrition of the lung-tissue. There is reason to believe too that this form of emphysema is sometimes associated with gout.

There is a form of lobular emphysema which is met with in old age, and which differs in some respects from that already described. The lungs are not so large; they are universally distended, however, to a greater or less extent, and they present a somewhat atrophied appearance. The alterations, of which they are the seat, are probably the result of those changes which age produces in the chest-walls, impairing their elasticity. This loss of elasticity may also affect the lung-tissue. See *LUNGS*. Atrophy of

A knowledge of the changes produced by emphysema affords an explanation of the peculiar character of the respiratory movements and

sounds, as well as of the other physical signs and symptoms of the disease. The lungs being the seat of general expansion, the thorax is kept abnormally distended. Thus it can undergo but little enlargement at each inspiration. As there is no impediment to the passage of air to the air-sacs, inspiration is accomplished rapidly. Not so, however, with expiration. The lung-tissue has in great measure lost its elasticity, and retracts slowly after distension; and this results in laboured, slow, and ineffectual efforts to expel the air. Further, as the lungs are more or less riddled with perforations, their vibrating surface is diminished, and this necessarily causes dyspnoea, whenever any increased demand is made on the respiratory function. The quantity of blood circulating through the lungs, even from the earliest stages of the affection, is also diminished; and the destruction of the capillary vessels, which ensues when the disease is more developed, further decreases the vascularity of the pulmonary tissue. Hence its pale, anæmic appearance after death, a circumstance which serves to explain how rarely it is the seat of pneumonic inflammation.

SYMPTOMS.—A constant and generally gradually increasing dyspnoea is one of the most important and most frequent of the symptoms of emphysema. Cough with expectoration is generally more or less present. Hemoptysis is rare, and when it does occur, is slight. The patient usually complains of no pain, but of a feeling of oppression, or a 'smothering in the chest.' In severe cases of lobular emphysema this last symptom and the dyspnoea are often the only circumstances which attract the attention of the sufferer to his malady. In other instances, however, and especially when the disease is only partial, a close examination will elicit the fact that there have been bronchitic symptoms. Few cases of emphysema exist for any length of time without the occurrence of asthmatic seizures. In advanced cases the aspect is peculiar. The countenance is dusky, lœdem, and puffy. The nostrils are dilated, and expand widely on inspiration, whilst the angles of the mouth are drawn down. The voice is feeble. The whole body has a cachectic appearance, and is sometimes much wasted. General dropsy often ensues.

PHYSICAL SIGNS.—Amongst the most important of the physical signs of emphysema are the following:—The upper part of the chest and the clavicles are prominent, the neck seems shortened, the fossæ above the clavicles are deepened; there is increased curvature of the dorsal spine; and the sternum is arched. The gait is stooping; the ribs are prominent; and the intercostal spaces are depressed. There is indeed a general increase in the size of the chest, usually most marked at the upper part. These are the features of the disease when it is extensive. If partial, or confined to one lung or part of a lung, the prominence of the chest exists on one side only, and the other symptoms and signs are less marked. The movements of the chest in respiration are peculiar. The breathing is for the most part superior thoracic, but the chest is not much expanded on inspiration, for the lungs are already inordinately distended. The lower end of the sternum and the lower ribs are drawn in

during inspiration. In some cases during inspiration there is marked protrusion of the abdomen. The respiration presents other features. The inspiration is short and quick, and is followed by a prolonged and often wheezing expiration. Coughing is performed feebly, and expectoration is attended with difficulty. Percussion and auscultation elicit important diagnostic marks of the disease. When it is general there is increased, and in some instances almost tympanitic, resonance over the whole of the chest, most marked towards the apices of the lungs, and along their anterior borders, and in partial cases almost confined to these spots, or to one side. The præcordial region is generally resonant, owing to the distended lungs coming between the heart and the wall of the chest; and the cardiac impulse can often be felt beneath the lower end of the sternum. The respiratory murmur is faint, and characterised by peculiarities which a knowledge of the anatomical condition of the lungs and of the chest-walls enables us to explain. The inspiratory murmur is short, and is followed by a prolonged expiratory murmur. This latter is unlike the sound heard in any other affection, and is, in fact, pathognomonic of emphysema. In some advanced cases the respiratory sounds are scarcely audible, if the bronchial tubes are free from mucus, and no spasm exist. Laennec described a *râle* which he thought was peculiar to emphysema. He called it '*râle crépissant sec à grosses bulles*.' A *râle* such as Laennec described is often heard in emphysema, but it is not a dry *râle*. It is probably produced in the finest bronchial tubes, and is a modification of the subcrepitant *râle* of bronchitis. Although valuable in aiding diagnosis when present, yet from its frequent absence and the difficulty of distinguishing it from the ordinary sup-crepitant *râle*, it loses much of its diagnostic import.

COMPLICATIONS AND SEQUELÆ.—Bronchitis is one of the most frequent of the diseases associated with emphysema of the lungs. It is rare for the latter affection to exist for any length of time without the supervenience of the former. Bronchitis presents some peculiarities when it affects an emphysematous lung. It is rather the result of congestion than of inflammation. It often attacks the finer bronchial tubes; and when severe, is attended with profuse secretion; a circumstance which, coupled with the fact that expectoration is less easily accomplished than when the lungs are healthy, seriously complicates the affection, and increases the danger of death from asphyxia. The inflammation sometimes runs on very rapidly, and copious purulent or puriform expectoration occurs. Even when this is the case, an examination of the tubes after death may reveal but little vascularity of the mucous membrane. These severe bronchitic attacks are very apt to be attended by the formation of fibrinous clots in the heart and the large vessels arising therefrom. Bronchitis, in a subacute or chronic form, is a very constant cause of winter cough in emphysematous patients.

Asphyxia, occurring with greater or less severity, is a frequent attendant on emphysema. The attack comes on for the most part during the night, and may possibly be due to the congestion

of the lungs which takes place during sleep, or when the body is long in the recumbent posture. This congestion probably sets up an irritation, which gives rise to reflex spasm of the bronchial muscular fibres.

Secondary affections of the heart are constantly met with in advanced cases of emphysema. Many pathologists have believed that the right cavities alone become affected; but more recent observations have shown that the cardiac disease is not confined to one side. There is, in extensive emphysema a general hypertrophy of the heart, with dilatation of all the cavities, especially of the ventricles. But hypertrophy is not the only change which takes place; valvular disease is frequently found. The deposits and thickening which occur about the valves are no doubt secondary to the changes in the muscular walls, and must be attributed to the general mal-nutrition produced by the disease. It is not difficult to understand how it happens that in emphysema there is general cardiac hypertrophy. The impediment which exists to the circulation of the blood through the lungs necessarily gives rise to an overloaded state of the right side of the heart, hence results increased action of the right cavities, and hypertrophy of their walls. Again, the overloaded state of the venous system, and the consequent impediment to the capillary and arterial circulation, call for increased action of the left ventricle; and this is followed by its dilatation and thickening. There exists also another cause, which probably has some influence in producing this cardiac hypertrophy, namely, the altered position of the heart. This organ is pushed downwards and towards the median line, and its impulse is often felt strongly in the epigastrium. The position of the ventricles is therefore changed, and the direction of the axis of their cavities is altered with reference to that of their great vessels. This must lead to enlargement of the circulation.

As a consequence of the changes in the heart and venous system in emphysema, dropsy often results. Many cases go on for a long time without any dropsical symptoms, whilst in others there is only slight edema of the legs. In advanced cases, however, there is frequently general dropsy.

General emphysema is attended in its progress with symptoms of cachexia and anemia. In some cases there is much wasting of the muscular system, even before dropsical effusions occur. Further, the patients often have a sallow and anemic appearance, not unlike that met with in renal and other serious organic diseases. There has been an impression that emphysema and phthisis are incompatible diseases, but recent researches have shown that this view is not correct. Indeed, in a large proportion of cases of death from phthisis, patches of emphysema, lobular or partial lobular, are met with; and doubtless have been produced by the fits of coughing so common in the disease. But the great question is whether tubercular deposit ever takes place in lungs which are the seat of lobar emphysema; and this question must be answered in the affirmative, although the concurrence of the two diseases is rare. Pneumonic consolidation is very uncommon in ac-

emphysematous lung, and probably acute so-called atrophic pneumonia never attacks the organ in such condition.

Pleurisy not unfrequently exists in connection with emphysema, pleuritic adhesions being often found after death. The occurrence of pleurisy must, however, be considered as an accidental circumstance. In the most extensive cases of emphysema pleuritic adhesions may not be found.

TREATMENT.—This must be referred to under two heads, namely (1) the treatment of the disease, and (2) that of the secondary affections, which follow or are associated with it.

(1) *Treatment of the disease.*—Too little attention has been paid to emphysema of the lungs as a substantive disease. Considered in the main as the result of bronchitic affections, the treatment has been chiefly directed to the control of these attacks; and in regard to the partial forms of emphysema, this is a most important object. But in reference to lobar emphysema, if we recognise the fact that it is primarily due to some degeneration of tissue, it is obvious that the treatment should be directed to check, if possible, this process. It can scarcely be expected that when once perforation and rupture of the air-sacs have taken place, the normal condition of the lung can be restored. But whilst we admit this, it is by no means implied that the disease is beyond control. That condition of lung-tissue which precedes the perforations—the simple distension of the air-sacs—admits of great amelioration, and further degenerative changes may be, if not prevented, at least much retarded.

The main principles of treatment should be such as guide us in the management of other constitutional diseases attended with degeneration. All measures which tend to invigorate the system, to give tone to the heart, and improve the condition of the blood, should be resorted to. Amongst the remedies for internal administration the most useful is iron. It should be given in small and continued doses. Quinine is valuable, as are also the various bitters and other remedies for dyspepsia, from which emphysematous patients often suffer. Cod-liver oil is very useful in some cases. Strychnia has been recommended with the view of improving the tone of the muscular fibres of the bronchial tubes. It has not been found useful in this respect; nor need we wonder at this, for the disease is one primarily of the air-sacs, and not of the bronchial tubes, and if the muscles of the latter are secondarily affected, it is rather with spasm than paralysis. Small doses of strychnia given for dyspeptic symptoms may be useful.

Breathing condensed air has been strongly advocated, and no doubt it has afforded in some cases decided temporary relief, but no permanently good effects have apparently ever followed its use. See AIR, Therapeutics of.

The regulation of the diet, and the general management are most important. The diet should be nourishing, and a moderate amount of stimulants should be allowed. The food should be easy of digestion, and nutritious in proportion to its bulk. The stomach should never be overloaded, as that condition will give rise to

dyspnoea. Errors of diet must be avoided, and the functions of the bowels should be carefully regulated. Another point is to give the lungs as little work as possible, and to let the patient breathe a pure air. All violent exercise, or physical exertion of any kind, must be strictly prohibited, moderate exercise is, however, to be recommended. Moderate walking, yachting, carriage exercise, riding at a quiet pace, and on an easy horse, are important adjuncts in the general treatment of emphysema. The condition of the skin should be carefully looked to; warm clothing should be constantly worn; and the greatest care should be taken to ward off bronchial inflammation. Residence during the winter in a warm and dry climate is to be recommended.

(2) *Treatment of secondary affections.*—Amongst the most important of the affections secondary to emphysema is bronchitis. No depressing measures should be used in this disease, but such as will promote expectoration, and check the secretion of the bronchial tubes, if, as is very frequently the case, this be excessive. Ammonia, the various stimulating expectorants, and iron are the most valuable remedies, together with moderate counter-irritation (see BRONCHITIS, Diseases of). The dyspnoea attendant on emphysema admits only of palliative treatment, but is often greatly improved by the observance of the rules laid down for the general management of the disease. The dyspnoea is always increased by the presence of bronchitis, by the stomach or bowels being overloaded; and by the general over-distension of the venous system, which necessarily ensues as a consequence of the impediment to the flow of blood through the lungs. Care should be taken to prevent any stultent distension of the stomach or intestines, and to keep up a good action of the bowels, liver, and kidneys. For the relief of the asthma which frequently exists in connection with emphysema, full doses of iodide of potassium are often useful. Stramonium may also be smoked, and other measures beneficial in ordinary spasmodic asthma may be tried (see ASTHMA). In reference to the treatment of the dropsical symptoms, which follow as a secondary consequence of emphysema, the reader is referred to the article DROPSY.

II. Interlobular Emphysema.—This condition, in which the excess of air in the lungs is contained not in the alveoli but in the connective tissue between the lobules, is described under the head of EMPHYSEMA, SUBCUTANEOUS.
A. T. H. WATKINS.

LUNGS, Gangrene of.—SYNON.: Fr. *Gangrène du Poumon*; Ger. *Lungenbrand*.

DEFINITION.—Death of a portion of the substance of the lungs.

Gangrene of the lungs is of two kinds, namely: (1) *diffused*, in which the whole of one lobe or lung is affected; and (2) *circumscribed*, in which a portion only of a lobe undergoes gangrenous change.

ÆTIOLOGY.—Gangrene is sometimes a result of acute pneumonia. It has been known to follow the inhalation of noxious gases. When it occurs independently of these causes, it is in evidence either of extreme constitutional depre-

sion, or of pressure interfering with the circulation and nutrition of the lung. An aneurism or mediastinal growth, pressing upon the main arterial, venous, and nervous trunks at the root of the lung, is perhaps the most common cause of diffused gangrene; whereas the more circumscribed form of the disease is a sequela of acute and limited pneumonia, cancer, or rapid phthisis in a debilitated subject. In pulmonary apoplexy gangrenous change sometimes occurs, the gangrene being limited to the portion of lung involved in the originating extravasation of blood. Pneumonia caused by a foreign body in the air-passages is apt to run on to gangrene. The diffused gangrene that occurs in drunkards and lunatics, in asthenic fever, measles, small-pox, and typhus, evidences excessive nerve-prostration and loss of nutritive power. In children gangrene of lung sometimes follows cancerum oris, as well as the eruptive fevers.

ANATOMICAL CHARACTERS.—The colour of a gangrenous lung is dark, dirty olive, or greenish brown. It is moist or wet; and either of the consistences of engorged lung, or softer and more diffident. The odour is that of external gangrene or decomposed flesh, and is distinctive during life, rendering the room in which the patient lies horribly offensive. When scattered patches of gangrene occur, there is often in one part a solid mass of greenish lung-tissue, and in another a central sloughy or gangrenous cavity, surrounded by a broad rim of soft, infiltrated lung. The seat of circumscribed gangrene is usually the periphery of the lung, and the lower lobes. If a bronchus open into the gangrenous patch, inflammation of the bronchial membrane is set up. In rare cases the pleura is involved, and pyo-pneumothorax induced. Sometimes the pulmonary arteries are found plugged, and more often the bronchial arteries. In those rare cases in which recovery takes place interstitial pneumonia is set up, leading to encapsulation of the gangrenous spot; the sloughs are ejected; and cicatrization follows, as in pulmonary abscess.

In diffuse gangrene the whole of one lung is sometimes involved. The pulmonary tissue is then converted into a black, putrid substance, saturated with blackish purulent fluid, or the gangrenous part merges gradually into oedematous or hepatised tissue.

Embolism, arising from the introduction of putrid matter into the veins, and leading to abscess in various organs, may follow either form of gangrene. Secondary gangrenous change is frequently met with in other parts of the same or of the opposite lung.

SYMPTOMS.—It is seldom possible to diagnose gangrene of the lung until the purulent discharge reaches a bronchus and is ejected. Then the sputa are found to soon separate into layers—a frothy superficial one, a liquid middle, and a lower sediment. The smell of the sputa and breath is pathognomonic. The dyspnoea and prostration are usually great. The physical signs are those of softening and excavation, percussion being either dull or tympanitic, and loose crepitation being soon replaced by gurgling and passing amphoric breathing. The passage of the gangrenous into the diffused form may be traced by watching the physical signs.

DIAGNOSIS.—Suppurative ulceration of the bronchial cartilages gives rise to great fetor of breath. Sometimes a gangrenous odour in the breath occurs when the putrefactive change is limited to the secretions, the lungs being free; and it is present also in pyo-pneumothorax with internal fistula. These several diseases must be excluded by a careful estimation of the history, and the physical signs.

PROGNOSIS.—The prognosis of pulmonary gangrene is hopeless in the diffused form; and should be made very cautiously, even when the symptoms or signs point to a limitation of the mischief.

TREATMENT.—Beside the general treatment which co-existing disease may require, special attention must be given to the removal of the gangrenous odour from the atmosphere of the room, from the sputa, and from the patient, who is apt to exhale from the skin a similar odour to that given off in the breath. Sulphurous acid, carbolic acid, or chloride of lime fulfil the first indication; Condy's fluid the second, and this may also, when diluted, form a useful wash, gargle, or drink. The sulpho-carbates, when administered freely, have a distinct value in removing the fetor from the skin, and making the patient less unapproachable.

When a gangrenous abscess of the lung exists, and it is evident that the passage of foetid matters through the bronchi is setting up dangerous irritation, leading to exhausting discharge, or threatening to poison the system, the question of tapping the gangrenous cavity should be entertained. The introduction of a drainage-tube sometimes affords immediate relief in such cases, the fetor of breath ceases, the offensive secretions, being no longer locked up in the lung, lose their putrescent character; and the relief to the constitution is great. An accurate diagnosis is in such cases essential, the danger of the operation being greatly enhanced if the abscess is at a distance from the chest-wall, and if the lung is not adherent to the costal pleura. The operation should only be performed when there is but little prospect of recovery without it, but must not be delayed until the vital powers are too reduced to allow of ultimate convalescence.

Every attempt must be made to support the strength by nourishing food and stimulants; bark and ammonia, quinine and acids, iron and cod-liver oil being indicated. The inhalation of creosote or carbolic acid in spray may be tried, or of turpentine given off from hot water.

E. SYMES THOMPSON.

LUNGS, Hæmorrhage into.—**SYNON.**: Extravasation of blood into the lungs; Pulmonary apoplexy; *Fr. Hémorrhagie du poumon*; *Ger. Lungenblutung*.

ÆTIOLOGY AND PATHOLOGY.—In the article HÆMOPTYSIS will be found enumerated the causes which lead to pulmonary hæmorrhage. In the present article only those extravasations of blood into the lungs are included which do not depend upon direct injury to the organ, or upon exposure and rupture of vessels in the course of destructive disease affecting it. Hæmorrhage into the substance of the lungs may be *diffuse*, *punctiform*, or *circumscribed*.

(1) *Diffuse pulmonary apoplexy*.—The diffuse extravasation of blood into the lungs is an extremely rare condition. Some cases have been recorded, however, in which it has arisen from primary disease of a branch of the pulmonary artery. The lung-tissue is broken down by the hemorrhage into it; and the patient soon succumbs.

(2) *Punctiform hemorrhage*, and (3) *circumscribed or nodular pulmonary apoplexy*, are not of uncommon occurrence, and are attendant upon the same morbid conditions of the lung. Mitral disease of the heart, mitral stenosis especially, but also mitral regurgitation, are the chief remote causes of these two forms of pulmonary apoplexy.

In certain purpuric states of system, which we need not here specify, punctiform hemorrhage in the lungs is possible; the purpura much more frequently affects, however, the pleural surface or bronchial mucous membrane. Mechanical congestion of the lungs from the above-mentioned forms of heart-disease is by far the most common condition upon which this minute and interstitial form of hemorrhage supervenes, giving rise to no additional symptoms, but causing considerable and peculiar pigmentation of the lung. The interstitially thickened lungs acquire a brownish tint, from the absorption of the blood-spots, leaving hematin behind, and the appearance has given rise to the term *brown induration* of the lungs. See LUNGS, Brown Induration of.

Nodular or circumscribed pulmonary apoplexy is often associated with the petechial hemorrhage just described, and like it mostly supervenes upon the mechanical congestion of the lungs arising from heart-disease. There are two ways in which this form of hemorrhage may be produced. The first way is by rupture of capillaries or small veins under the heightened pressure of the pulmonary circulation. An effusion of blood thus occurs, which fills up one or more lobules, and coagulates to form the dark firm consolidations so characteristic of the lesion. Or a branch of the pulmonary artery becomes obstructed by an embolus, for instance, by a fragment of coagulum conveyed from the right auricle, or from one of the systemic veins, and its territory becomes at once filled with blood, in the following manner. The pulmonary arterial vessels do not communicate with one another, each branching separately to its capillary distribution; the pulmonary veins, on the contrary, anastomose freely, and, moreover, are not provided with valves. Thus when the onflow of blood is arrested through the obstructed branch, venous regurgitation through the capillaries from collateral pressure fills up the precluded vascular area with stagnating blood, and the intra-alveolar tissues become speedily occupied with its effused corpuscles. In some cases the vessel may not at first be accurately closed by the embolus; the onward current is then retarded instead of being quite arrested; the mechanism is, however, practically the same.

ANATOMICAL CHARACTERS.—A lung, the seat of this form of hemorrhage, is usually toughened and heavy. Some hard, and more or less square, flat surfaces may be felt and seen raised above the general surface of the lung,

which has shrunk below their level. The pleura covering such patches is darkened in colour, and presents flakes or granulations of lymph, impairing its translucency and smoothness. On making a vertical section through one of the surfaces, it is found to form the base of a more or less conical mass, which has a firm damson-cheese-like section, and is sharply defined from the surrounding tissue. In its axis is seen a branch of the pulmonary artery, occupied by partially altered clot. There is usually some staining of the pulmonary tissue immediately surrounding the apoplectic nodule, from imbibition. Such hemorrhagic nodules vary greatly in number and size; there are usually several in each lung, of about the size of a walnut, but one may occupy a whole lobe. They also vary in appearance according to the date of their occurrence; their colour, at first that of dark blood-clot, passes through pale chocolate or catechu tint to yellowish red or pale yellow, as the colouring matter becomes gradually absorbed. The whole extravasation may be gradually and completely absorbed, leaving the restored lung but little damaged, or a shrunken fibrous deposit or blood-cyst, with surrounding induration, may mark the site of former hemorrhage. It should be added that these extravasations, although generally near the pleural surface of the lung, are not always so, but may occur deeply in its substance.

SYMPTOMS.—Amidst the distressing symptoms which are attendant upon the conditions leading to pulmonary apoplexy, it would be difficult to single out any diagnostic of this special lesion. An exacerbation of dyspnoea already terrible enough, or a sudden failure of pulse, may perhaps be noted. Dark scanty hemoptysis is, however, the pathognomonic sign, the frothy mucous expectoration containing some streaks, or small clots of dark coagulated blood. Some circumscribed patches of dulness, with bronchial breathing and neighbouring crepitation, may be made out, especially in the mammary and mid-axillary regions.

PROGNOSIS AND TREATMENT.—These lesions are among those which close the scene in the heart-disease to which they are accessory; they are therefore irremediable. Sometimes when, from any cause, their occurrence appears to have been hurried forward, when the lividity is great, the dyspnoea urgent, and yet the disease is not of long duration; wet-cupping or bleeding from the arm will certainly give great temporary relief, and perhaps avert immediate danger.

R. DOUGLAS POWELL.

LUNGS, Hydatids of.—SYNON.: Fr. *Kystes hydatiques du pommou*; Ger. *Lungenecthecoccus*.

DEFINITION.—A disease due to the presence of hydatids in the lungs.

ÆTIOLOGY.—Hydatid cysts in the lungs rarely occur in this country as a primary disease of the lung, but they are not infrequently met with as an extension of disease from the liver.

The general causes of hydatid disease are elsewhere discussed, but the circumstances which determine the localisation of the hydatid are not clearly ascertained. In Australia, where the affection is very common, it is met with

sometimes in the lung without any other organs being affected; although in many cases in which the lungs are diseased, evidence of the existence of the same disorder elsewhere is not wanting. In 100 cases, the liver was the organ affected in 70, the lung in 12. The great prevalence of the disease in Melbourne is said to be due to drinking from water-holes frequented by sheep, and from eating watercress or uncooked salads containing the ova of the parasite.

ANATOMICAL CHARACTERS.—The general anatomy of hydatid disease will be found in the article describing this parasite (see *HYDATIDS*). Single sacs of accephalocysts are by far most usual, varying in size from a pigeon's egg to a man's fist. Sometimes the upper, and sometimes the lower lobes are the seat of the cysts. They are developed in the interstitial pulmonary tissue; as growth proceeds, the neighbouring parenchyma is converted into fibro-cellular tissue, and undergoes obsolescence. The parent sac, containing the echinococci, is adherent to the surrounding tissue.

If the parent sac be destroyed by inflammation and consequent suppuration, a communication is established between the cavity and the bronchi, through which the daughter-cysts may be ejected; just as in more common instances they may escape from the liver after perforating the diaphragm and lung. Not unfrequently the pulmonary sac communicates with a similar sac in the liver. It is natural to infer in such cases that the disease originated in the liver. Indeed, it has been stated that primary hydatid of the lung is unknown.

SYMPTOMS AND PHYSICAL SIGNS.—Hydatids may exist in the lung for a considerable time without giving rise to any noticeable symptoms; but as the tumour enlarges, and presses upon the surrounding tissues, hæmoptysis occurs, as also bronchitis, pneumonia, or even gangrene. Sometimes the cysts perforate the pleura and cause pneumothorax, or make their way through the diaphragm into the abdominal cavity. The more usual course is the converse of this, namely, that a hydatid of the liver exists perhaps for years, causes abdominal distension, and eventually discharges its contents through the diaphragm into a bronchus; then expectoration of blood occurs, with gooseberry-like skins, varying in size from a nut (in which case the cyst may be expelled whole) to an orange (in which case the sacs are shrivelled and empty), causing straining and suffocating cough during expulsion.

If the site of the tumour be superficial, altered breath-sounds and percussion-note may be observed, but if it be deeply seated, the physical signs may escape detection. If bronchitis or pneumonia be set up, the signs and symptoms of these disorders mask those of the originating disease. Often the symptoms are like those of rapid phthisis, namely, cough, mucopurulent expectoration, hæmoptysis, night-sweats, and emaciation. The meaning of these symptoms is apparently confirmed by the physical signs, namely, dulness on percussion; absence of breath-sounds, or prolonged expiratory murmur; and, when the cysts burst, gurgling and pectoriloquy. Unless the daughter-cysts or hooklets are expectorated, there is nothing to point unmistakably to the

nature of the disease. When perforation of the diaphragm occurs, hepatic symptoms or those of pleurisy occur. The patient looks anxious, the features are collapsed; the skin is clammy and livid; the extremities are cold; incessant paroxysmal cough occurs, with vomiting; and, by degrees, pallor and jaundice make their appearance. Symptoms of acute pneumonia may occur—of consolidation, followed by excavation, the expectoration being at first rusty, then biltinged, mucopurulent, and foetid, and containing, besides shreds of lung-tissue, entire cysts or portions of them.

DIAGNOSIS.—It may be difficult to distinguish a large hydatid cyst from pleuritic effusion, as the lung may be displaced, the chest bulges, and the intercostal spaces become prominent and fluctuating. The rounded outline of the dull space, the absence of acute symptoms, the history of gradual onset, the absence of ægophony, and of alteration of physical signs on change of posture, will guide the decision, and an exploratory puncture, which gives exit to a clear saline, non-albuminous fluid, containing possibly hooklets or fragments of cysts, will confirm the diagnosis. The conduction of the heart-sounds and impulse, and the tense unyielding condition of the bulged side on palpation, may lead to the suspicion of mediastinal tumour, but in the case of hydatids there is seldom any visible venous engorgement, or laryngeal or œsophageal pressure-sign, as in aneurismal or other mediastinal growths. There is, moreover, generally a freedom from cachexia or constitutional disturbance. In circumscribed abscess the neighbouring lung is rarely so free from disease as in hydatid.

PROGNOSIS.—Although the symptoms may be so severe as to threaten immediate death from suffocation, recovery occurs in at least half the cases in which hydatid disease begins in the lung, and one-third of those in which it spreads from the liver. If the cyst is allowed to burst of itself, recovery takes place in from 30 to 40 per cent. of cases. But the mortality is greatly reduced by early tapping.

TREATMENT.—Palliative treatment must be directed mainly to the mitigation of pain, and other urgent symptoms. Curative treatment consists in destroying the vitality of the cyst. If the fluid contents are drawn off, or allowed to escape, the death of the hydatid may occur, or inflammatory action, leading to suppuration. If the fluid re-collect and pressure-signs recur, iodine or other stimulating fluid may be injected. The iodide or bromide of potassium with kaulin have gained among Australian physicians reputation in these cases, especially when combined with the use of the trochar.

E. SYMES THOMPSON.

LUNGS, Hyperæmia of.—*SYNON.*: Congestion of the Lungs; Fr. *Hypérémie du pommou*; Ger. *Lungenhyperæmie*.

DEFINITION.—Excess of blood in the lungs, whether local or general.

VARIETIES.—Pulmonary hyperæmia may be active, passive, or obstructive.

The morbid appearances and symptoms are different in these three kinds of hyperæmia, and they may, therefore, be best considered separately.

A. Active Hyperemia of the Lungs.—

SYNOM. : Active congestion ; active affluxion.

DEFINITION.—A determination of blood to the lungs.

ANATOMICAL CHARACTERS.—Active hyperemia or congestion may affect any portion of the lung, which remains crepitant and little changed, save that it is more crimson in colour, and contains slightly more blood than natural. The condition is indeed rather a vital or physiological one, and, as in active hyperemia of the skin, may present no *post-mortem* appearances. On section, however, the lung usually exudes some frothy serum, tinged with blood; and sometimes, especially when the hyperemia is local and arises from collateral stroma of circulation, there is found hæmorrhage into the lung. The mucous membrane of the bronchial tubes is minutely injected, or it may be quite natural in appearance.

ÆTIOLOGY.—The causes which produce inflammation of the lung will also produce active hyperemia, namely, cold, irritation, adjacent inflammation, &c. Increased action of the heart during violent effort or excitement, whether from mental emotion or from drink, will produce the same effect. It is said that the pressure of blood in the pulmonary artery increases more rapidly than that in the aorta during exertion (Colin). Hæmoptysis from pulmonary hyperemia is commonly produced by the excessive inhibition of stimulants. Predisposition, either hereditary or in consequence of present disease, renders these last-named causes much more readily operative. Obstruction to the passage of blood through one portion of the pulmonary system of vessels, for example, by embolism, or by destruction of capillaries, will cause increased collateral activity of circulation. Sudden suppression of menstruation may cause active determination of blood to the lungs. Sudden diminution of the atmospheric pressure within the chest, as during violent inspiratory effort, whilst the trachea is closed, for instance, in croup, laryngismus, or whooping-cough, may cause active determination of blood to the lungs.

EFFECTS.—Several important effects may be produced by active hyperemia of the lungs. Hæmorrhage is rarely extensive, unless there be attendant organic lesion present. Active hyperemia of the lung constitutes the first stage of exudative or croupous pneumonia, with fibrinous exudation into the air-cells. Pulmonary edema may result from the excessive blood-pressure, the serum exuded being frothy and blood-tinged. Vesicular catarrh is not so distinctly a consequence of hyperemia, with which, however, it is often associated.

SYMPTOMS.—The symptoms of active pulmonary hyperemia are dyspnea; more or less pyrexia; cough; and sometimes copious hæmoptysis, in which case preëxistent organic disease must be suspected. The rusty sputa of the first stage of pneumonia is that most typical of pulmonary hyperemia.

DIAGNOSIS.—The diagnosis would rest mainly upon the suddenness of attack, and the evidence of a sufficient determining cause, with or without predisposition.

PROGNOSIS.—Active hyperemia, save in some cases of collateral afflux, is necessarily a tran-

sient affection, subsiding in a few hours, or passing on to inflammation.

TREATMENT.—The first point in the treatment of this condition is to secure absolute rest in bed, with silence, and removal of all causes of excitement. Derivatives, mustard or linseed poultices to the chest; perhaps cupping, or even blood-letting; warmth to the extremities; saline purgatives; and a low diet, without stimulants, may all be employed. The special cause of the hyperemia should be treated. As a rule astringent medicines should be avoided. Digitalis is useful to calm the circulation, especially after excitement from alcohol. If the pyrexia be very marked, pneumonia may be expected, and saline diaphoretics are especially indicated.

B. Passive Hyperemia of the Lungs.—

SYNOM. : Passive or hypostatic congestion.

DEFINITION.—An incomplete stagnation of blood in the lungs.

ÆTIOLOGY.—Passive or hypostatic congestion of the lung is a condition of hyperemia affecting by preference the most depending parts of the lung. Failure of heart-power, an inability to propel the blood clear through the pulmonary capillaries, is the chief cause of this condition. In states of exhaustion from low fevers, especially typhus and typhoid; after severe surgical operations, in extreme old age; or towards the end of prostrating illness, this failure of heart-power, and consequent stagnation of blood in the lower parts of the lung, usually the bases, is apt to supervene, and is one of the common modes of death. An altered condition of the blood, so as to render its passage through the capillaries more difficult, is also stated to be a cause of this form of congestion of the lungs and of other organs. In uræmic and icteric conditions, and in the febrile state, the blood does not pass through the capillaries with the same facility as in health, and hypostatic congestions are more apt to occur. Finally, when the vessels have lost their tone, and the heart fails in power, gravitation exercises its influence in attracting the blood to the most dependent parts.

ANATOMICAL CHARACTERS.—Passive hyperemia almost always affects the bases of both lungs, although often not in an equal degree, the difference depending mainly upon the position of the patient during the last days of life. The affected lung is dark-coloured, and engorged with dark blood. Its tissue is more or less deeply stained with blood, and is less crepitant than natural, yielding also more readily than natural under the pressure of the finger. If thoroughly washed, however, in a gentle stream of water, the lung-texture will be found to be but little altered. This condition very readily passes into a low form of pneumonia, and thus portions of the lung may be found consolidated, having much the appearance and consistence on section of a congested spleen (splenification, hypostatic pneumonia). The bronchial tubes and pleura are affected by *post-mortem* staining.

SYMPTOMS.—The symptoms of this form of congestion of the lungs are lividity, especially of the lips and extremities; and quickened shallow breathing; superadded to those of extreme prostration. Dulness on percussion, with anæsthetic

breathing and moist crepitant *râle*, are found over the bases of both lungs, but in greatest extent on that side to which the patient has been inclining.

TREATMENT.—Passive hyperæmia of the lungs being never the primary affection, and always being a sign of failing power, its treatment consists in vigorously supporting the patient by alcoholic stimulants frequently administered, with nutritious food. Nutritive enemata are often of great value. In all exhausting diseases this condition should be anticipated, and warded off if possible by timely support and stimulants, and above all by frequently turning the patient from one side to the other, thus calling in the aid, rather than permitting the hindrance, of gravitation to the circulation through the lungs. Of medicines, ammonia, ether, bark and quinine are of the greatest value, and musk, sumbul, and lavender may be useful adjuncts.

C. Obstructive Hyperæmia of the Lungs.

SYNOK. : Mechanical congestion.

DEFINITION.—Hyperæmia from obstruction to the escape of blood from the lungs. Mechanical congestion of the lungs is a condition differing essentially from either of the two preceding.

ETIOLOGY.—The origin of this form of hyperæmia is purely secondary and mechanical, and is included in that of the primary disease. The obstruction may be at the mitral valve, as in mitral stenosis or regurgitation, or, again, the obstruction may be at the left ventricle, when this cavity is dilated and imperfectly emptied, as in the advanced stages of constrictive or regurgitant aortic disease. Whether there be an absolute narrowing of the blood-channel between the pulmonary and systemic circulations, that is, at the mitral orifice or at the commencement of the aorta; or whether, from enlargement of the mitral orifice or from disease or injury of its valve, regurgitation be permitted, so that each contraction of the right ventricle is met and opposed, more or less, by a counter rush of blood from the left ventricle—in any case, and still more in the combination of two or more of these causes, it is clear that the pulmonary circulation can only go on at an increased pressure by the contraction of the right ventricle becoming more vigorous; and thus hyperæmia must result from the damming back of the blood through the pulmonary veins.

Of the causes named, mitral constriction is that which leads most simply to obstructive hyperæmia of the lungs.

ANATOMICAL CHARACTERS.—It is obvious that obstructive hyperæmia is of general distribution, affecting the whole of both lungs. The result of the heightened blood-pressure from increased force of injection into the lungs, to overcome an impediment to the escape of blood from them, is most felt in the pulmonary capillaries. These capillaries gradually become lengthened, tortuous, and dilated even to three times their normal dimensions (Rindfleisch). From chronic engorgement of the lungs, the nuclei of the interlobular areolar tissue and of the connective tissue surrounding the minute vessels and bronchi, and pervading the parenchyma, proliferate. The thickened and tortuous capillaries intrude upon

the air-spaces; and the elasticity of the lungs being also impaired, their vital capacity is diminished. It is stated that the muscular fibres, which proceed from the bronchial terminations to form loops upon and encircle the infundibula, become hypertrophied (Rindfleisch) thus, perhaps, compensating for a diminution in the more mechanical elastic property of the lung. Sometimes minute hæmorrhages take place into the parenchyma of the lung; sometimes larger escapes of blood fill the alveoli of circumscribed patches (pulmonary apoplexy). The total result of the intimate changes described, is an uniform increase in the size and weight of the lungs, with an increased density and toughness. On section the lungs are found to be more pigmented and solid-looking than natural, sometimes of a brownish hue (brown induration), they are, however, crepitant throughout, except here and there, where they may present the firm, dark, damson-cheese-like section, buding to brown-red, of recent pulmonary apoplexy. There may be some œdema present. The pulmonary arteries and veins are enlarged and congested, and the bronchial mucous membrane is usually the seat of chronic catarrh. Patches of atheroma are frequently to be seen in the larger branches of the pulmonary artery.

SYMPTOMS.—Dyspnoea and cough, both brought on or increased by effort, with palpitation, and oppression or tightness, usually referred to the epigastrium, are the most constant symptoms of obstructive hyperæmia of the lungs. Patients suffering from this condition have repeated attacks of bronchial catarrh, and hæmoptysis is of common occurrence. The hæmoptysis may be considerable, but usually the expectoration is streaked with blood or contains small dark coagula.

This form of hyperæmia commonly occurs before middle life, during the usual period of mitral heart-disease. The signs of heart-disease, and most often of constriction of the mitral valve, are present. The subjects of this disease are often undernourished and badly nourished, the pigeon-breasted type of chest being common, especially in those cases in which the disease manifests itself early in life. Small, frequent pulse, more or less lividity of lips, and other signs and symptoms of the cardiac disease, of which the pulmonary condition is the consequence, are to be observed. A fine inspiratory crepitant *râle* over the lungs may be heard. During the repeated bronchial catarrhs, with increased pulmonary hyperæmia, to which such patients are especially prone, all symptoms are much aggravated.

DIAGNOSIS.—The existence of obstructive heart-disease suggests the presence of corresponding hyperæmia of the lungs. The fine crepitant *râle* and the hæmorrhagic symptoms and signs more positively point in the same direction.

PROGNOSIS.—The prognosis rests chiefly upon the heart-condition present. Increasing frequency of catarrhal complications, and especially of hæmoptysis, shows the turning of the balance against the patient. The condition may in favourable cases continue for years, especially when dependent upon simple constriction of the mitral valve.

TREATMENT.—The treatment is essentially that of the heart-disease; with the avoidance of all causes which hasten respiration, and which tend to produce catarrhs, to which these patients are so especially prone. R. DOUGLAS POWELL.

LUNGS, Hypertrophy of.—**DEFINITION.**—Enlargement of the lungs, with increased functional power. A condition only clinically met with as a compensatory affection of one lung, or of a portion of one lung, to make up for more or less loss of pulmonary tissue by disease.

ETIOLOGY AND PATHOLOGY.—The process by which hypertrophy of the lung comes about is almost a mechanical one. Destructive disease having removed a large portion of one lung, or permanent collapse or blocking of such portion having occurred from any cause, the diminished power of the affected lung to occupy its apportioned space in the chest-cavity during inspiration, is compensated for by an increased expansion of the healthy lung, together with a certain recession of the softer parts of the chest-wall on the affected side. The increased expansion of the healthy lung encourages an increased afflux of blood, which is at the same time determined through it by the partial obstruction to circulation through the diseased lung. These changes taking place gradually, the increased function and increased afflux of blood are, in accordance with our experience of similar conditions in other parts, attended with increased nutrition of the lung, and its true hypertrophy is thus little by little established.

Hypertrophy of the lung, therefore, is not a diseased condition, but an excessive development in consequence of injury to some other portion of the same or of the opposite lung. Its occurrence may be best noted during the gradual absorption or removal of a pleural effusion, which has long compressed the opposite lung. Any disease, however, which, after destroying or placing in abeyance a certain proportion of one lung, becomes arrested, tends to cause hypertrophic development of the remaining lung. Chronic pneumonia, cirrhosis, arrested phthisis, and atelectasis in the child, are the chief diseases of the kind. While disease is actively progressive the conditions present—namely, fever, anorexia, and pleuritic pains, are unfavourable to the extra development of the sound lung, but when these unfavourable conditions subside, the hypertrophy proceeds with great rapidity, and may be established in a very few months. The effect of the rarefied air of mountainous regions is to develop the natural capacity and function of the lungs.

ANATOMICAL CHARACTERS.—An hypertrophied lung is larger and heavier than natural, and its anterior and inferior margins are thick and rounded, and are found to extend beyond their normal thoracic limits both laterally and inferiorly. The texture of the lung is firmer and more resilient than usual; and it is plentifully supplied with blood. The air-cells are slightly enlarged, but not obviously dilated; and on microscopic examination the nutrition of the alveolar walls and capillaries is found to be perfect; there being neither the thinning of the alveoli, nor the excessive growth of fibrous tissue met

with at different stages of so-called 'hypertrophic emphysema.' Nor are the capillaries tortuous and dilated as in the indurative 'hypertrophy' of the lung from heart-disease.

Extent of lung affected.—We have considered, for the sake of simplicity of description, those cases in which the whole of one lung is hypertrophied, and such cases are very common. But a single lobe of a lung may become hypertrophied, the seat of the hypertrophy depending upon the seat of the disease to which it is compensatory. But, except when the pulmonary destruction is limited and circumscribed, other conditions come into play, and we are more apt to get emphysema than hypertrophy. It may be said then that hypertrophy of the lung is (at least so far as we can appreciate it clinically) a one-sided affection, except in those cases in which it has been occasioned by some general external cause, as rarefied air.

PHYSICAL SIGNS.—The side on which is the hypertrophied lung is expanded, both relatively (the opposite side being usually flattened and contracted) and absolutely. The nipple-level is raised. There is increased percussion-resonance over the side, extending across the median line, so that sometimes the line of resonance indicating the inner margin of the enlarged lung will reach the mid-clavicular vertical line of the opposite side. The lower limits of resonance are also extended in front and behind. The respiratory murmur has that peculiar coarse vesicular character, with somewhat prolonged expiration, which is known as 'puerile' or 'exaggerated' respiration. The heart is more or less displaced towards the contracted side, and the displacement is often apparently increased by the heart becoming on the one side covered by the expanded lung, and on the other side unduly exposed by the recession of the diseased lung. This is especially the case when the hypertrophy affects the left lung. There are no morbid sounds heard over the enlarged lung unless (as in many cases of phthisis) it becomes or has been affected by disease. With the expansion of the lung the general symptoms improve, and the dyspnoea lessens.

DIAGNOSIS.—The diagnosis has to be made between hypertrophy of the lung; hypertrophic emphysema; and mere dilatation. The unilateralness of the hypertrophy; its arising secondarily to some disablement of the opposite lung; the absence of precedent or present general bronchitis or asthma, together with the obscurity of its occurrence being commensurate with improvement in the condition of the patient, are the main features distinguishing it from large-lunged or hypertrophic emphysema. Nor could the puerile breathing of hypertrophy be easily confounded with the short, weak, or inaudible inspiration, and wheezy prolonged expiration of emphysema. In persons of broken constitution, with contractile disease of one lung, the opposite lung may become dilated and assume the shape and dimensions of hypertrophy; but the breathing of the patient does not improve, the respiratory sounds are enfeebled, and it is clear that the condition present is one of emphysema rather than true hypertrophy.

PROGNOSIS.—The prognosis is always per

to be favourable to the patient, the hypertrophy being an important element of his recovery.

TREATMENT.—Compensatory hypertrophy of the lung is a condition carefully to be encouraged, when all active symptoms attendant upon the original disease are past. Mild courses of calisthenics, and a temporary sojourn at some elevated health-resort during the warm season, are most valuable, if not attempted too soon. Abundance of fresh air throughout the year, with the careful avoidance of fresh catarrhs, such as may be obtained by spending a winter and spring or two seasons at the South of France, in Italy, or at Madeira; or a well-planned sea-voyage to Australia, are excellent ways of spending months of convalescence. A generous unstimulating diet is indicated, and tonic remedies and cod-liver oil are useful, more especially in the early stages of the wished-for hypertrophic development.

R. DOUGLAS POWELL.

LUNGS, Induration of.—See **LUNGS, Inflammation of.**

LUNGS, Infarction of.—See **LUNGS, Hemorrhage into.**

LUNGS, Infiltrations of.—Certain morbid formations in the lung assume the arrangement of an infiltration, the tissues, especially the interlobular cellular tissue, being permeated with the morbid material. In some instances it involves even the epithelial cells. The best examples of this arrangement are observed in connection with certain cases of the fibroid change; in infiltrated cancer; and in those forms of pulmonary disease where the lung-tissue is the seat of a deposit of substances introduced from without, being inhaled in various occupations, such as particles of carbonaceous matter and coal-dust, stone-grit, iron-dings, particles of cotton or wool, and other materials. Albuminoid disease, and some forms of pigmentary change also present a kind of infiltrated arrangement. These conditions need not be further considered here, as they are discussed in their several appropriate articles.

FREDERICK T. ROBERTS.

LUNGS, Inflammation of.—SYNON.: *Pneumonia*; Fr. *Pneumonie*; Ger. *Lungenentzündung*.

DEFINITION.—The term 'pneumonia' has been employed simply to designate inflammation of the lung-tissue. Inflammatory processes in the lungs, however, occur under such diverse circumstances, and are accompanied by such diverse clinical phenomena and histological changes, that 'pneumonia' used in this sense includes widely different diseases.

VARIETIES.—Pneumonias are divisible into the following varieties:—A. *Acute Pneumonia*; B. *Secondary Pneumonias*; C. *Broncho, Catarrhal, or Lobular Pneumonia*; and D. *Chronic or Interstitial Pneumonia*. In addition to these there are those intense and concentrated forms of pulmonary inflammation which lead to the formation of *abscess*.

There are certain other forms of lung-consolidation which have sometimes been described as *pneumonia*, but which are really, for the most part, non-inflammatory in their nature, and will, therefore, be only briefly alluded to in the present

article. These are:—(1) that condition of collapse and hyperæmia, mainly due to weak inspiratory power, feeble circulation, and gravitation, which is so common in the more dependent portion of the lungs in many acute and chronic diseases (see *HYPOSTATIS*); (2) Consolidations of the lung resulting from mechanical congestion and embolism, such as are met with in certain diseases of the heart, &c. See *LEUCIS*. Hyperæmia of

The several varieties of pulmonary inflammation must now be considered separately in the order just indicated.

A. Acute Pneumonia.—SYNON.: Fr. *Pneumonie aiguë*; Ger. *Cruppige Pneumonie*.—This is pneumonia *par excellence*. It is the disease to which some would be inclined to restrict the application of the term. It is often termed *cruppous pneumonia*, from the supposed resemblance of the histological process to that of croup. It is also known as *lobar pneumonia*, inasmuch as a large area of the lung is usually involved in the inflammation.

DEFINITION.—Pneumonia may be described generally as an acute disease, characterized clinically by sudden onset, severe febrile symptoms, cough, expectoration, and dyspnoea, by the physical signs of pulmonary consolidation, and by a rapid abatement of the general symptoms between the fourth and tenth days. Anatomically it is characterized by an acute inflammation of the lung-tissue, and by the accumulation of the inflammatory products within the alveoli, which products consist, in the main, of a fibrinous exudation and leucocytes.

ÆTIOLOGY.—*Atmospheric influences.*—Conditions of weather and climate are probably the most important of all known agencies in the causation of pneumonia. The influence of cold and damp in increasing the liability to acute inflammatory diseases of the chest is well known. This influence is marked in pneumonia, although to a much less extent than in bronchitis. Pneumonia is more common in temperate climates than in those regions which are characterized by great heat or extreme cold. Climates and seasons which are liable to sudden changes of temperature, and winds from the north and north-east, appear to be especially favourable to this disease.

Age.—Acute pneumonia is met with between the ages of one and five years. Here, however, it is liable to be confounded with broncho-pneumonia and with collapse of the lung, so that the results of statistics are less reliable at this than in the subsequent periods of life. It may be stated notwithstanding, that acute pneumonia is less common during infancy than has been generally supposed, and that amongst the pneumonias which are so frequent during this period of life the broncho-catarrhal forms preponderate. After the age of five years the liability to pneumonia diminishes, but it again becomes exceedingly frequent between the ages of twenty and forty, during which period the liability to the disease reaches its maximum. It is also quite common in old age.

Sex.—In adults more males than females suffer. This is probably owing to the former

being more exposed to atmospheric influences. In early life this difference does not obtain.

Social position, &c.—Pneumonia is more common amongst the poor and badly fed, and amongst those whose occupation necessitates an irregular mode of life and great exposure, than amongst the upper classes of society.

Constitution, and health.—Those who are constitutionally weak, and those whose general health has been impaired by some temporary cause, are more prone to the disease than the strong and vigorous.

Previous diseases.—True pneumonia, as is well known, sometimes occurs in those who are the subjects of other diseases. It is impossible to speak with certainty as to the relation which subsists between the pneumonia and the disease in the course of which it supervenes. In some cases it may be merely an accidental complication, whilst in others the previous disease may exercise more or less influence in the causation of the pneumonia. Most of the pulmonary consolidations, however, which occur in the course of other diseases do not belong to the category of true pneumonia, but are either local inflammations, caused by some abnormal state which the pre-existing disease has induced, or conditions of hyperæmia and collapse, in which an inflammatory process plays but little part.

Exciting causes.—In many cases of acute pneumonia evidence of the existence of any exciting cause is entirely wanting. Of discoverable causes, that which is most common is a sudden chill or less frequently, more prolonged exposure to cold and damp. Excluding cold, no conditions can be mentioned which have any marked influence in determining the disease.

ANATOMICAL CHARACTERS.—The changes occurring in the lungs in acute pneumonia are commonly described under the three following heads:—

1 *Stage of engorgement.*—This is the stage of inflammatory hyperæmia and œdema, and it is characterised microscopically by overfulness and slight tortuosity of the pulmonary capillaries, and by swelling of the alveolar epithelium. The lung is of a dark red colour, it is heavier and less crepitant than natural, it pits on pressure; and its cut surface yields a reddish, frothy, tenacious liquid.

2 *Red hepatisation.*—Here there is an exudation of liquor sanguinis and blood-corpuscles. The exuded liquids coagulate within the alveoli and terminal bronchioles, the coagulum enclosing numerous white and a few red blood-corpuscles. The alveolar epithelium is swollen and granular. It is stated by some German pathologists that the coagulum is in part produced by changes in the epithelium. The lung is now much heavier than in the preceding stage, and is increased in size, so as to be often marked by the ribs. It is quite solid, sinks in water; and cannot be artificially inflated. It is remarkably friable, breaking down with a soft granular fracture. The cut surface has a markedly granular appearance, seen especially when the tissue is torn, and due to the plugs of coagulated exudation matter which fill the alveoli. The colour is of a dark reddish-brown, often here and there passing into grey. This admixture with grey

sometimes gives a marbled appearance. The pleura covering the solid lung always participates more or less in the inflammatory process. It is opaque, hyperæmic, and coated with lymph.

3 *Grey hepatisation.*—This stage is characterised by a continuance of the process of inflammatory cell-emigration, and by cell-proliferation. The white blood-corpuscles continue to escape from the vessels, and the alveolar epithelium multiplies. The alveoli thus become more completely filled with young cell-forms, so that the fibrinous exudation is no longer visible as an independent material. Many of these cells, especially those in the vicinity of the alveolar walls, are larger than leucocytes and nucleated. These are evidently the offspring of the alveolar epithelium. The fibrinous exudation now disintegrates, and the young cells rapidly undergo fatty metamorphosis. The alveolar walls themselves, with few exceptions, remain throughout the process unaltered, although very occasionally, when this stage is unusually advanced, they may be found here and there partially destroyed. Owing to these changes, the reddish-brown colour of the lung becomes altered to a greyish or yellowish white. The granular appearance is much less marked; the solid tissue is much softer and more pulpy in consistency, and a puriform liquid exudes from the cut surface of the organ. This stage, when advanced, has been termed 'suppuration' of the lung.

Although these three stages of the pneumonic process have been described as succeeding one another in orderly succession, it must be remembered that each stage does not occur simultaneously throughout the whole of the affected area of the lung. The changes advance unequally, so that whilst one portion of the lung is in the stage of red hepatisation, another may be in the grey stage—hence the mottled, marble appearance of the consolidation. The rapidity with which the several stages succeed one another is also subject to marked variations. In some cases the pneumonic consolidation very rapidly becomes grey, whilst in others the time occupied in the transition is much longer. These differences will be again alluded to when considering the clinical history of the disease.

Resolution.—The natural and almost invariable termination of the histological process is in *resolution*—the lung gradually returning to its normal condition. This is effected by the fatty and mucoid degeneration, and consequent liquefaction, of the inflammatory products which have accumulated within the alveoli. As the liquefaction proceeds, the circulation in the alveolar walls is gradually restored, the softened products are removed by absorption, and to a much less extent by expectoration; and the lung ultimately regains its normal characters. The other exceptional modes of termination in *gangrene*, *abscess*, and *chronic pneumonia* will be alluded to subsequently.

Site.—The local lesion in acute pneumonia is in the majority of cases limited to one lung. When double, one lung is usually involved before the other. The right lung is more commonly affected than the left. The part of the lung usually involved is the lower lobe (about 75 per cent.). The consolidation may extend upwards and implicate

the whole lung. Pneumonia of the upper lobes is more frequently double than *basal disease*. It is quite rare for the pneumonic process to commence in two different portions of the lung. When the consolidation is met with in both lungs, or commencing in the upper and middle lobes, the pneumonia is often either a secondary affection, and has supervened in one whose health has been previously injured, as by alcohol, and such distributions of the local lesion should always make the physician look carefully for evidence of some pre-existing disease.

PATHOLOGY.—Acute pneumonia is undoubtedly to be regarded as a general disease, of which the pulmonary inflammation is the prominent local lesion. The view that it is a strictly local affection of the lung, to which the pyrexia and other symptoms are secondary, is altogether untenable. The truth of this statement becomes obvious from a study of its natural history. The disease, as will be seen subsequently, runs a typical course. The pyrexia bears no definite relation to the lung-affection. It frequently precedes it by a considerable interval, and commonly disappears suddenly, and long before the resolution of the pulmonary consolidation.

Respecting the exact nature of the disease, however, we are at present unable to speak definitely. It is maintained by some observers that, like the specific fevers, it is due to a specific cause. Pneumonia, whilst differing from those fevers in not being contagious, resembles them in the typical character of its clinical phenomena, and to a less extent, of its local lesion. The changes in the lung occurring in pneumonia cannot be induced by artificial injury of the organ, and it must therefore be admitted that there is something special in the inflammatory process. Pneumonia appears to be most closely allied to tonsillitis and acute rheumatism, and like these diseases the circumstances under which it originates are certainly exceedingly diverse.

SYMPTOMS.—The onset of acute pneumonia is in the majority of cases sudden, not being accompanied by any premonitory symptoms. Much less frequently certain premonitory symptoms precede the more severe phenomena which characterise the invasion of the disease. These symptoms include general malaise, headache, chilliness, pains in the back, and loss of appetite.

Invasion.—The invasion in adults is, in almost all cases, announced by a rigor. This rigor is more marked in pneumonia than in almost any other disease. The rigor is usually single, and is rarely repeated, either at the commencement or in the course of the illness. In very old subjects the rigor is very frequently absent, and in children its place is often taken by convulsions or vomiting. The rigors or other phenomena marking the invasion of the disease, together with the attendant pyrexia, are usually quickly followed by symptoms pointing to the lung-affection. These symptoms commonly supervene in the course of from twelve to twenty-four hours, although in exceptional cases not until after the lapse of two or three days. The earliest of them are pain in the side, dyspnoea, and cough. These are local symptoms, together with the pyrexia, reddening of pulse, thirst, and prostration,

gradually develop up to the second day of the disease, by which time (and sometimes before this) the pulmonary lesion is usually sufficiently far advanced to yield unequivocal physical signs. The general aspect and symptoms of the patient are now tolerably characteristic. The flushed and sometimes dusky face, anxious expression, hurried breathing, hot skin, rapid pulse, short frequent cough, and marked prostration, supervening quickly upon the well-marked initial rigor, indicate pretty clearly the nature of the disease.

Pain.—The pain in the side, which is increased by deep inspiration and by cough, usually corresponds in situation with that of the affected lung, although it is occasionally experienced in other parts. This symptom may occur coincidently with, although it more commonly succeeds, the rigor. In quite exceptional cases it precedes it, being the first symptom noticed. Respecting its cause—it is probably due to the implication of the pleura in the inflammatory process.

Respiratory phenomena.—Increased frequency of respiration, dyspnoea, and cough, are early and prominent symptoms. The respiration—usually regular—ranges from 30 to 50, and in children reaches even to 70, whilst the pulse may be only from 90 to 120. This perversion in the pulse-respiration ratio is important in diagnosis. The breathing is shallow; inspiration is abrupt; and when the pain in the side is severe, respiration is sometimes irregular. The accelerated respiration is accompanied by marked expansion of the *ale nasi*, and by more or less dyspnoea. There is, however, no definite relation between the last-named symptom and the frequency of the respiratory act. Owing to the pain, and to the frequency and difficulty of breathing, speech is interferred with and often rendered exceedingly difficult. Cough is an almost constant symptom, except in the very old. It is short and hacking, rarely paroxysmal like that of bronchitis. It is usually in the early stages attended with severe pain in the side, so that the patient endeavours to repress it. The cough, except in children, and often in the old, is attended by expectoration. The sputa of pneumonia are very characteristic. They are viscid, glairy, and remarkably tenacious, so that they cling to the mouth of the patient, and adhere closely to the sides of the vessel containing them. In colour, they present various shades of red, brown, and yellow, owing to the admixture of blood. The appearance so well known as 'rusty,' is that most commonly met with. Sometimes they are much more diffuent, and of a dark purple colour, somewhat resembling prune-juice. The characteristic sputa are usually met with on the first or second day of the disease, but their appearance is often preceded by a frothy aerated expectoration like that of bronchitis. The amount expectorated is small, and sometimes the pneumonic is associated with more or less of the frothy catarrhal sputa throughout the whole of the disease. During the period of resolution the sputa become less viscid and more catarrhal in character, and they usually contain small particles of black pigment. The histological elements met with in the sputa are leucocytes, red blood-cells, and altered epithelium from the alveoli and air-pass-

sages, and towards the decline of the disease, fat-granules, pigment and occasionally fibrinous masses, which are casts of the alveoli and terminal bronchioles.

Pulse.—The pulse in adults usually ranges from 90 to 120, and it may be even more frequent. It is commonly much more rapid in children, and less so in the old. In the early stage of the disease it is often full and strong, but it soon becomes smaller and easily compressible. It may be irregular, intermittent, or dichrotous. The smallness of the pulse is probably due partly to diminished cardiac power, and partly to the diminished amount of blood which is propelled from the left ventricle, owing to the overloading of the right cardiac cavities which results from the obstructed circulation in the lungs.

Pyrexia.—The pyrexia of pneumonia is continuous, with slight morning remissions and evening exacerbations. The temperature rises very suddenly with the invasion of the disease, to from 102° to 105° Fahr.; and this high temperature is maintained until the period of crisis. This sudden rise and maintenance of a high temperature is very characteristic. The amount of elevation varies in different cases. As a rule it does not exceed about 104° or 105° Fahr., but temperatures of 107° have been known to terminate favourably. In fatal cases it may reach 109° shortly before death. The maximum temperature is usually met with on the second or third day of the disease, but it occasionally occurs immediately before the crisis. The daily variations are usually as follows.—The temperature is lowest about 7 or 8 A.M. In the forenoon, or somewhat later, it commences to rise, and attains its maximum in the early evening. It then falls, but a slight exacerbation occasionally occurs again at midnight, after which it gradually falls. The difference between the highest and lowest temperatures is usually not more than 1° Fahr. The pyrexia runs, for the most part, a uniform course until the period of crisis, when the temperature falls rapidly, in the manner to be hereafter described.

Nervous system.—Headache, restlessness, and sleeplessness are almost always prominent symptoms. Slight delirium is also common, especially towards evening, when the pyrexia is at its maximum. Sometimes the delirium is more marked and violent. It constitutes a more prominent symptom in the old, and in the debilitated and intemperate. In drunkards it is constantly present, and here it often assumes the character of delirium tremens. Convulsions are common in children, especially at the period of invasion. They are rare in the adult. These nervous symptoms are sometimes so prominent as to mask the nature of the disease.

Digestive organs.—The symptoms of acute pneumonia referable to the digestive system are similar to those met with in other severe febrile diseases. There is loss of appetite and thirst. The tongue is more or less thickly coated with a white fur, and it tends in severe cases to become dry and brown. Herpes often appear about the lips, and sometimes on other parts of the face, about the third or fourth day of the disease. Vomiting, which is a common symptom of invasion in the child, is an occasional compli-

cation, as is also diarrhoea; constipation, however, is the rule.

Urine.—The quantity of urine is considerably diminished, and its specific gravity increased, so that abundant urates are deposited. The excretion of urea is greatly increased, and it may amount to as much as seventy-five grammes in the twenty-four hours. The uric acid is likewise augmented. The chloride of sodium is much diminished, and during the height of the disease it may entirely disappear. Slight temporary albuminuria is perhaps more common in pneumonia than in almost any other acute febrile affection. The amount is usually in direct proportion to the severity of the disease. Bile-pigment is occasionally met with.

COURSE AND TERMINATIONS.—The symptoms which have been described continue with often increasing severity up to about the end of the first week of the disease, sometimes longer, when an improvement usually occurs. This improvement may take place quite suddenly, and the disease rapidly terminate in health—termination by *crisis*; or the recovery may be more gradual—termination by *lysis*. In other cases death occurs either before or after the crisis. The disease may also terminate in *gangrene* of the lung, in *pulmonary abscess*, or in *chronic pneumonia*. These several modes of termination must be considered separately.

Complete recovery.—This is the most common termination of acute pneumonia in young and healthy adults, and the improvement usually occurs quite suddenly—by *crisis*. The time at which this crisis takes place, as indicated by the sudden fall of temperature, varies from the third to the twelfth day. In the majority of cases it is on the fifth, sixth, or seventh day; it is occasionally as early as the third day, and sometimes it is prolonged into the middle of the second week. The old doctrine that the crisis always occurs on the odd days is untenable.

The superintention of the crisis is sometimes indicated by a change in the pulse, which becomes softer, and somewhat irregular in force and rhythm. The most marked phenomenon attending it is the abrupt fall of the bodily temperature. This fall may commence either during the morning remission or the afternoon exacerbation. It appears to be most common late in the afternoon. The temperature very often reaches the normal standard in from sixteen to twenty-four hours, usually within forty-eight hours, the morning remission and evening exacerbation occurring during the period of desferescence. The temperature not unfrequently falls to 1° or 2° Fahr. below normal, and may remain so for two or three days. Occasionally a marked increase in the pyrexia is observed immediately before the commencement of desferescence.

With the fall of temperature all the symptoms rapidly improve. The skin becomes moist and often perspires profusely. The amount of urine increases. The respiration falls in frequency, and, to a less extent, the pulse. The cough becomes looser, and the expectoration more copious; the sputa gradually losing their tenacity and rusty colour, and becoming more rheumatic in character. They are now usually

tingled with more or less black pigment. An improvement in the physical signs is sometimes observed at the same time; more commonly, however, this does not take place till one or two days later. The patient often falls into a deep sleep, and on waking, with the exception of great weakness, declares himself pretty well and begins to ask for food. In some cases, however, the amount of prostration following the crisis is so great that the return to health is more gradual, and a condition of collapse may ensue which may even terminate in death.

In the majority of cases acute pneumonia terminates abruptly in the manner above described. Sometimes, however, recovery is more protracted, and deferment may not be complete till the end of the second week, the temperature falling more gradually—by *lysis*. The critical fall of temperature is occasionally interrupted by more or less marked exacerbations, due either to the implication of fresh portions of the lung, or to the supervenience of one of the complications to be hereafter alluded to. In some cases, again, after the occurrence of the crisis, the temperature assumes a hectic type, and does not quite reach the normal standard for perhaps two or three weeks, the irregular fever being due probably to the contamination of the blood by the absorbed pneumonic products (Parkes). Lastly, a distinct relapse may occur after the completion of crisis, but the relapse is in most cases shorter and less severe than the primary attack.

Death.—When pneumonia terminates fatally, it usually does so towards the end of the first, or quite at the beginning of the second week. Death is commonly due partly to failure of cardiac power, and partly to apnoea. Apnoea is the least important element in the causation of dissolution. The danger from it increases with the extent of lung involved, and it is consequently usually greater in double than in unilateral disease. Failure of cardiac power is undoubtedly the most important means by which pneumonia destroys life (Juergensen). There are several conditions in the disease which tend to damage the contractile power of the heart. First and foremost of these is the pyrexia. The severe pyrexia of pneumonia, like that of other acute febrile diseases, produces more or less granular degeneration of the cardiac muscular fibres. It also necessitates increased frequency of the cardiac contractions, in order to supply the increased demand for oxygen, and to remove the excess of carbonic acid. Owing to this increased frequency, the length of diastole—the period during which the heart rests and is nourished—is shortened. The condition of the lung itself constitutes another important element tending to damage the contractile power of the heart, and especially of the right ventricle (Juergensen). The lung-consolidation not only presents more or less obstruction to the pulmonary circulation, and hence necessitates increased action on the part of the right ventricle; but owing to the diminished respiratory surface, this ventricle is obliged to do more work in order that the proper interchange of gases may be effected in the lungs.

Such being the modes by which pneumonia

tends to destroy life, it will be readily understood that the earliest and most important signs of unfavourable augury are on the side of the circulation. The pulse becomes more frequent, small, irregular, and often dichrotonic. The frequency of the respiration, the dyspnoea, and the cyanosis increase. The cough becomes feeble and ineffectual. Owing to the engorgement and failure of power of the right ventricle general pulmonary oedema usually supervenes, so that moist *râles* are audible at both bases. The extremities become cold, and there is often profuse perspiration. The mind wanders and a condition of partial coma supervenes before the close. In some cases a rapid rise of temperature takes place before the fatal termination, whilst in others there may be a considerable fall in the thermometer.

Pneumonia may also terminate fatally from the state of collapse which follows the crisis. Lastly, in those exceptional cases in which the pneumonia tends to become more or less chronic, death may occur during the third or fourth week. Death may also result from the complications.

Gangrene.—This is quite rare. It is most common in chronic drunkards, and in those of debilitated constitution. Its occurrence appears to be due partly to blocking of vessels, and partly to the septic influence of altered inflammatory products. It is usually limited to a small area of the pneumonic lung, and is either diffuse, or becomes limited by a zone of inflamed tissue. It commonly supervenes late in the disease, and the most reliable signs of its occurrence are marked fetor of the expectoration, and great prostration. Portions of lung-tissue are occasionally found in the sputa. It is almost invariably, but not necessarily, fatal.

Abscess.—This is somewhat more common than the preceding. See LUNGS, Abscess of.

Chronic pneumonia.—Acute pneumonia in very exceptional cases becomes chronic, and leads to induration of the lung. See D. Chronic Pneumonia.

PHYSICAL SIGNS.—The earliest physical signs of acute pneumonia are usually discoverable within forty-eight hours of the invasion of the disease. They often appear within twelve or twenty-four hours, but occasionally, when the local lesion is deeply seated, nothing abnormal is to be detected until the third or fourth day. It will be well to describe them in the order in which they commonly make their appearance. The time occupied in their evolution will vary according to the rapidity with which the several stages of the pneumonic process succeed one another.

The earliest abnormal physical signs are due to the pain caused by the movement of the affected side; to the hyperæmia of the pulmonary capillaries; and to the commencing exudation into the air-vesicles. The respiratory movements of the side are more or less impaired. This is partly owing to pain, and partly to diminished elasticity of the lung-tissue. The breath-sounds are usually somewhat weak and harsh, but not distant; although, as stated by Stokes, they are occasionally in the earliest stage harsher and louder than natural. Per-

crescendo during this stage is usually not markedly altered. The resonance, however, is sometimes quite appreciably tympanitic, but as the disease progresses the tone becomes impaired. The tympanitic quality of the resonance is caused by the diminished elasticity of the still air-containing lung. The vocal fremitus is increased. The most important sign, however, of the congestive stage is *fine crepitation*. This *r le* consists of a number of fine, dry, crackling sounds, following one another in rapid succession, which have been aptly compared by Dr. C. J. B. Williams to the sounds produced by rubbing the hair between the fingers close to the ear. It occurs during the later period of this stage, when the process of exudation from the pulmonary capillaries is commencing to take place. Its production is probably due to the partial agglutination of the walls of the air-vesicles and their forcible separation during the inspiratory act. The *r le* is almost exclusively limited to inspiration. It is intensified by deep inspiration and also by cough, and it is sometimes necessary to make the patient cough in order that it may be produced. A precisely similar *r le* is often heard with deep inspiration in portions of the lung which have been imperfectly expanded. Such imperfect expansion is common in the posterior parts of the lungs of patients who have been confined to bed from acute or chronic disease, and in whom, owing to muscular weakness, inspiration is incompletely performed. The *r le* produced under these circumstances is distinguished from pneumonic crepitation inasmuch as it completely disappears after a few deep inspirations, whereas the pneumonic *r le* when once established persists until the consolidation of the lung is tolerably complete.

The physical signs of the stage of hepatization are due to the more or less complete consolidation of the lung. The fine crepitation which characterised the later periods of the preceding stage continues during the process of consolidation, but ceases as the filling of the air-vesicles becomes complete, although it may often still be heard at the confines of the more firmly consolidated lung. It occasionally happens, however, when the consolidation is very rapidly induced, that no crepitation is heard throughout the course of the disease until the period of resolution. When the lung has become consolidated, the expansive movement of the corresponding portion of the chest, which was before diminished, ceases. The intercostal spaces, although sometimes slightly more prominent than in the healthy side, are still depressed and not obliterated as in pleural effusion. When the amount of exudation is very considerable, slight enlargement of the side is necessarily produced. The situation of the cardiac impulse is not altered. The vocal fremitus is usually increased. To this general rule, however, there are exceptions, and it not unfrequently happens that it is unaltered, and it may even be completely absent. This diminution in the vocal fremitus is sometimes due to the blocking of the smaller bronchi with the inflammatory exudation, but more frequently it appears to result from an accumulation of

mucus. In the latter case it may sometimes be restored by cough. Coincidentally with the increase of vocal fremitus there is usually increased vocal resonance, and sometimes whispering pectoriloquy (Walshe and Wilson Fox). The percussion-sound now is much more deficient in tone, and it is often more or less amphoric. This amphoric quality is probably obtained from the column of air in the larger bronchi and trachea. There is also a great increase in the sense of resistance, but neither the dulness nor the resistance are so marked as in pleural effusion. In basic disease percussion under the clavicle often yields a distinctly amphoric note, whilst the lower portions of the chest may be almost absolutely dull. The auscultatory sign of this stage is bronchial breathing. This is usually remarkably superficial, high-pitched, and metallic in quality (tubular breathing). Sometimes, however, it is less metallic and softer (diffused blowing—Walshe). These respiratory phenomena, like the vocal resonance and fremitus, may be absent over larger or smaller areas of the consolidated lung, owing to the obstruction of the bronchi by catarrhal secretion. The slight pleurisy which constantly accompanies the pneumonia is rarely susceptible of physical demonstration during this stage. This is probably owing to the immobility of the solid lung. During the period of resolution, as expansive power returns, friction-sounds are occasionally audible.

Resolution usually commences in those portions of the lung which were the last to become consolidated. The most important and the earliest of the signs of resolution is the return of crepitation. The crepitation, however, differs from that met with in the earlier stages of the disease. It is larger, coarser, and more liquid in character—*redup crepitation*, and its liquid character gradually increases until it may become distinctly bubbling. When resolution is very rapid, redup crepitation may be absent (Wilson Fox). The bronchial breathing now loses its metallic ringing quality, the percussion-dulness gradually disappears, and the respiration regains to a great extent its normal characters.

The commencement of resolution and of the improvement in the physical signs occasionally takes place, as already stated, coincidently with the establishment of crisis, but more commonly it is not observed until from twenty-four to forty-eight hours after the temperature has reached the normal standard. The time occupied in the completion of resolution varies. Sometimes all physical signs almost completely disappear in twenty-four hours. Usually, however, resolution is less rapid, and marked signs of consolidation remain for periods varying from two or three days to two weeks. A slight amount of dulness and some weakness of respiration often persist at the posterior and inferior portions of the lung for even still longer periods. This is especially the case if the pneumonia is complicated with pleurisy. When marked signs of consolidation exist after the third week, there always exists more or less probability that the pneumonic process may become chronic.

VARIETIES. — The three following varieties of pneumonia present clinical phenomena com-

what different from those which have been described.

a. Latent pneumonia.—Pneumonia has been termed *latent* when the characteristic symptoms of the disease are absent, or but little pronounced; or when they are masked by some other clinical phenomena. It is in the pneumonia of the aged that marked latency is so often observed. Here invasion may be unattended by rigor or other prominent symptoms. Cough, expectoration, pain, and dyspnea may be completely wanting. If cough be present the sputa often do not present the rusty tinge, but are simply transparent or mucopurulent. Pyrexia, some increased frequency of breathing, great prostration, and more or less muttering delirium, are the principal symptoms. The fever, however, is usually much less than in adults. This latent course of pneumonia it is important to bear in mind, as it indicates the necessity of making a most careful physical examination of the chest in all severe acute illnesses of the aged. In the pneumonia of drunkards and of young children, also, the accompanying nervous phenomena may be so prominent as to mask the nature of the disease.

b. Asthenic (typhoid) pneumonia.—When pneumonia occurs in those who are debilitated by previous disease, by the abuse of alcohol, by age, by privation, or other causes, the phenomena of invasion are usually not pronounced, and symptoms of intense prostration occur early. In many respects the course of the disease closely resembles that which has been just described as so common in the aged. The initial rigor and pain in the side are often observed, but cough is slight; and the expectoration, instead of the rusty-brown tint, may present a dirty brown or prune-juice appearance. Various symptoms of an asthenic type soon become prominent; the most important of which are low delirium, alternating with stupor, tremors, and paralysis of the sphincters. The tongue is brown and dry; sores form on the teeth, the pulse is exceedingly rapid and feeble, and there is often slight jaundice and albuminuria. Death usually supervenes some time during the second week of the disease. After death the lung is usually found to be less firmly consolidated and less granular than in asthenic forms of pneumonia. The stage of grey hepatization in some cases is exceedingly advanced, constituting what has been termed 'suppuration' of the lung (Stearns).

c. Intermittent pneumonia.—An intermittent variety of pneumonia is sometimes met with in malarial districts, which appears to be one of the results of malarial infection. According to Grisolle it occurs in intermittent and remittent forms. The former is characterized mainly by the complete intermissions which occur in the pyrexia. The temperature falls suddenly at the end of twenty-four hours; profuse sweating occurs; and the physical signs of the pneumonia almost entirely disappear. A return of the pyrexia and physical signs takes place at the expiration of twenty-four or forty-eight hours, followed by another intermission, and this by a third or fourth, the disease presenting either a quotidian or a tertian type. Both lungs are

liable to be involved. In the remittent form there is a much less complete disappearance of the physical signs during the remission.

Complications.—*Pleurisy.*—Pleurisy of slight intensity and unaccompanied by effusion is, as already stated, almost invariably met with in acute pneumonia over those portions of the lung which are consolidated. This is natural to the disease, and cannot be regarded as a complication. Pleurisy of greater intensity, and attended by effusion, occurs in from five to fifteen per cent. of the cases. Signs of effusion are not usually discernible before the third or fourth day of the disease. The amount of liquid varies with the extent of the lung-consolidation. When this is considerable, involving nearly the whole lung, there is but little room for effusion. The superposition of pleurisy does not commonly materially modify the course of the disease. It may, however, protract the period of deferescence. Its influence in interfering with the disappearance of the physical signs has been already alluded to. When pleurisy occurs on the side opposite to the pneumonia it constitutes a more dangerous complication.

Bronchitis.—This is also a common complication, especially in the aged and in young children. Many cases, however, which have been described as acute pneumonia associated with bronchitis, have doubtless been cases of bronchopneumonia. The bronchitis almost invariably affects both lungs. Its superposition is attended by an increase in the cough and in the amount of expectoration. When it involves the smaller tubes generally, it constitutes a serious complication.

Pericarditis.—This is less frequent. It may result from the direct extension of the inflammatory process from the pleura, or it may be a part of the general disease. It is a grave complication, and greatly increases the mortality.

Jaundice.—A slight yellowish tinge of the conjunctiva, and even of the skin, is not unfrequent in pneumonia, and has no clinical significance. It is probably in most cases owing to the congestion of the liver which results from the impeded pulmonary circulation—the distended portal vein pressing upon the bile-ducts. Much more extensive jaundice is also occasionally met with, which appears usually to be due to duodenal catarrh, and is attended by gastric symptoms. In other cases, especially in asthenic forms of the disease, a non-obstructive jaundice sometimes occurs, resulting from changes in the red blood-corpuscles. This is commonly associated with nervous symptoms, such as stupor, delirium, and a tendency to collapse, which are of grave prognostic import.

Purulitis.—This is a very rare and exceedingly serious complication. According to Grisolle, it is usually unilateral, the inflammatory process is very acute; and commonly leads to supuration or gangrene.

Diagnosis.—The diagnosis of acute pneumonia, although usually easy, is sometimes attended with difficulty. It cannot be made with absolute certainty before the appearance of the physical signs of pulmonary consolidation, although some of the phenomena of invasion are so characteristic that the nature of the disease

is often tolerably evident before abnormal physical signs are discoverable. The phenomenon which age of the most diagnostic value at this early stage of the disease are the pyrexia, the altered pulse-respiration ratio, the pain in the side, and the cough. The sudden and rapid rise of the bodily temperature, which usually reaches its maximum in forty-eight hours, is very characteristic; such a rapid attainment and maintenance of a high temperature being perhaps more common in pneumonia than in any other disease (Wilson Fox). Of the other symptoms, the increased frequency of respiration, and especially the alteration in the pulse-respiration ratio, are of the most valuable diagnostic import (Walsh). When physical signs of pulmonary consolidation are discoverable, which they usually are within forty-eight hours, the diagnosis becomes certain.

Difficulties in diagnosis may arise in those cases in which the local process in its earlier stages is deeply seated. Here, characteristic physical signs may be wanting for four or five days, during which time some doubt may exist as to the nature of the disease. Then again in those latent forms of pneumonia which have been already described the disease may be easily overlooked, unless a careful examination be made of the chest.

The diagnosis of pneumonia from other diseases of the lungs is rarely difficult. The disease with which it is most liable to be confounded is pleurisy. In pleurisy, however, there is not, as a rule, such a sudden and rapid attainment of a high temperature as in acute pneumonia, and when effusion has taken place, the physical signs are in most cases sufficiently distinctive. In pleural effusion the bulging of the side; the obliteration of the intercostal spaces, the displacement of the heart, the absolute dullness and absence of resonance on percussion, the weak and distant character of the respiration, and the diminished vocal fremitus and resonance, contrast with the signs of pulmonary consolidation.

Another disease with which pneumonia may be confounded is that somewhat rare form of very acute phthisis, in which a large area of the lung becomes rapidly consolidated—the consolidation being often in the main indistinguishable histologically from that met with in acute pneumonia. Here, however, although the whole lung may be involved, the disease usually commences in the upper lobes, so that abnormal physical signs are more marked at the apex. The onset of the disease also is commonly much less sudden, and its course is more protracted. Then, again the rapid consolidation of the lower portions of the lungs which sometimes supervenes in more chronic forms of phthisis, might be mistaken for the consolidation of acute pneumonia, but the history of the case, a careful examination of the upper lobes of the lungs, the irregular course of the pyrexia, and the protracted duration of the disease, will easily serve to distinguish them. It may be stated generally that, in all acute consolidations of the lung, a protracted course of the pyrexia, and the occurrence of marked exacerbations and of remissions at the fever at irregular intervals, afford grounds

for the supposition that the consolidation is phthisical.

The diagnosis of acute pneumonia from broncho-pneumonia and collapse of the lung, will be considered when treating of broncho-pneumonia. See Broncho-Pneumonia.

Prognosis.—The mortality from acute pneumonia varies at different periods, the disease being more fatal in some years than in others. This is probably partly owing to variations in what is called 'epidemic influence.'

Of all the circumstances which influence the prognosis of pneumonia, that which is perhaps the most important is the state of the general health. In weakly subjects and in those whose constitutions have been damaged by previous disease, by privation, or by their mode of life, acute pneumonia is exceedingly dangerous. The prognosis is, however, especially grave in those injured by the long-continued abuse of alcohol, the mortality being, according to Hues, from 20 to 25 per cent.

In healthy children the mortality from pneumonia is comparatively small. The fatality formerly ascribed to the disease at this period of life was probably owing in great measure to the inclusion of cases of collapse and broncho-pneumonia in the statistics; the latter disease being exceedingly fatal. Healthy young adults rarely die, after the age of thirty the mortality increases considerably, and in the old pneumonia is an exceedingly fatal disease.

Pneumonia is more fatal in females than in males, the mortality being in the proportion of three to two. Pregnancy renders the disease more dangerous.

The danger of pneumonia increases somewhat with the extent of lung implicated. It is, however, the implication of both lungs which renders the prognosis especially grave. With regard to the situation of the consolidation it may perhaps be stated generally that pneumonia is commencing in the upper lobes are rather more serious than basal disease. The gradual extension of the consolidation into the disease, and the spreading of the inflammatory process from one centre to another, constitute elements of gravity. When resolution is much protracted, the fact that the disease in very exceptional cases terminates in an indurative consolidation of the lung is not to be forgotten.

The mortality of pneumonia is greatly increased by the existence of complications. The prognostic importance of these has already been considered.

Of individual symptoms the pulse is of chief importance. A pulse which in the adult is persistently over 120, and in the child over 140, is of grave significance. Marked irregularity in force and rhythm is also unfavourable, especially in the young. Diarrhoea may occur temporarily in quite favourable cases, but if it persists it indicates danger. The variations in respiration are of less import. An extreme quickness of breathing, marked dyspnoea, and cyanosis are not uncommon in cases which terminate in recovery; at the same time such symptoms must have more or less unfavourable significance. Sputa of a dark prune-juice colour are of somewhat evil augury, as is also an

abundant liquid puriform expectoration. The indications from the pyrexia are of less prognostic value in pneumonia than in most other acute diseases. A temperature of 105° or 106° Fahr. does not in itself indicate danger. Greater elevation is grave. In many fatal cases the temperature never attains 102°. The significance of a protracted defervescence has already been alluded to. On the side of the nervous system, it is to be remembered that slight delirium is not uncommon; but when it is marked, and especially when it occurs late in the disease, it is most grave. It is of greater significance in adults than in children. Tremors and a tendency to coma are also unfavourable. A dry, brown tongue is unfavourable, especially when associated with only a moderate degree of pyrexia. Gastric catarrh and diarrhoea add to the danger. A slight amount of jaundice is not of bad import. The existence of albuminuria or the appearance of albumen in the urine early in the disease, is unfavourable.

TREATMENT.—In considering the treatment of acute pneumonia, it is of the utmost importance to bear in mind the true nature of the disease. All rational and successful therapeutics must be based upon the recognition of the fact, that it is in general, and not a local, affection which we wish to influence. The 'heroic' methods of treatment by congestion, tartar emetic, &c., so much in vogue in the past, had for their object the controlling or cutting short of a local affection of the lung, hence the unfavourable results which attended them. As these methods have been abandoned, and there has existed more correct appreciation of the pathology of the disease, the mortality attending it has diminished.

When discussing the pathology of pneumonia, reasons were adduced for the belief that it owes its origin to a specific cause. Whether this be so or no, the disease is so closely allied to the specific fevers, that in attempting to influence its course by treatment, we must be guided by the same general principles. As in those fevers, our object must be to endeavour to conduct the pneumonia to a favourable termination. We cannot arrest its progress, but we can often do very much both to maintain the strength of the patient, and to modify those elements in the disease which tend to destroy life.

The modes by which pneumonia tends to destroy life have been already considered. Failure of cardiac power is the great source of danger. The causes of this failure it is important to bear in mind when treating the disease, and the reader is referred to what has been already stated respecting it. The natural course of the disease is also to be remembered. In the strong and robust pneumonia usually terminates in health. It is in those who are debilitated by age, privation, mode of life, the abuse of alcohol, or pre-existing disease, that such great mortality attends it. It is a question of the intensity of the disease on the one hand, and of the resisting power of the individual on the other. Such considerations as these not only indicate the importance of doing all that is possible to husband and support the strength of the patient, but also of not interfering too actively with the disease,

unless circumstances arise which, if uninfluenced by treatment, would tend to rapidly prove fatal.

Such being the general principles which should guide the practitioner in the treatment of acute pneumonia, the manner in which they are to be best carried out may now be indicated.

The patient should be kept in bed. The room should be large and airy, and the temperature about 60° to 62° Fahr. It should be well-ventilated. A plentiful supply of fresh air is most important, and although drafts should be exercised in the ventilation, there is not the same necessity to keep the patient scrupulously protected from draughts, as in the treatment of acute bronchitis.

The diet should be carefully regulated, nutritious, and easily digestible, consisting of milk, milk with the white of egg, beef-ten, meat essence and such-like articles, given in varying quantities and at varying intervals, according to the condition of the patient. With the object of promoting the appetite, it is well to keep the mouth cleansed with glycerine and lemon-juice. Small quantities of wine, as hock, dry sherry, champagne, or burgundy, given occasionally with food, are often useful as stimulants to the appetite and digestive process. Some acid and bitter, as hydrochloric acid and orange peel, may also be prescribed for the same purpose. If in the early stage of the disease there is great constipation, loaded tongue, nausea, or other gastric symptoms, the administration of a small dose of calomel or of blue pill and colocyath, is often followed by marked improvement, both in the power to take food, and in the general condition of the patient. The exhibition of purgatives, however, requires great care as they occasionally set up a catarrhal condition of the intestine, and consequent diarrhoea, which may prove more or less persistent. It is important, therefore, except in such cases as those above indicated, to procure all necessary evacuation of the bowels either by a small dose of castor oil, or of colocyath and hyoscyamus, or by simple enemata.

Everything should be done to husband the strength of the patient, and the services of an efficient nurse will often do very much towards the attainment of this object. Perfect rest must be enjoined, and all unnecessary speaking be forbidden. There are two circumstances which often tend greatly to interfere with rest, the pain in the side, and the cough. The former of these may usually be relieved by the application of large hot linseed poultices, or of hot fomentations to the side. These must be frequently changed, and great care should be exercised in their renewal not to disturb or inconvenience the patient. If these means do not succeed, from one-eighth to one-sixth grain of acetate of morphia may be administered hypodermically, or a small blister or three or four leeches may be applied to the seat of the pain, and the hot applications then renewed. Cough is not usually a troublesome symptom, and unless it greatly disturbs the patient, it is better not to interfere with it. If necessary, a liniment, containing from two to four minims of liquor morphia hydrochloratis and a similar quantity of virum speocmanha, given occasionally, is

often beneficial. By means of the treatment above indicated, and by keeping the room quiet and darkened, the patient will often procure a sufficient amount of sleep. This can very frequently be promoted by carefully sponging the whole surface of the body, a portion at a time, with tepid water, the last thing at night. Should it be necessary, some narcotic must also be administered, but with great caution, so as not to interfere with freedom of expectoration, and it should only be had recourse to when other means have failed, and in the absence of contraindications. Hyoscyamus and bromide of potassium may be safely used for this purpose, and should these fail, opium may also be given. This should be prescribed in a sufficiently large dose to ensure sleep, and is perhaps best administered hypodermically, as acetate of morphia. Chloral is usually contraindicated, on account of its depressing effect upon the circulation.

A very large number of cases of pneumonia terminate in health without the necessity of any further interference on the part of the physician than has been described. Frequently, on the other hand, circumstances arise indicative of danger, which require to be met by more active treatment. The chief source of danger, as already stated, is failure of cardiac power, and consequently all symptoms of such failure must be carefully watched for. Apnoea is less important, except in those cases where both lungs are extensively involved.

Any sign of cardiac failure will in the first place suggest the advisability of administering alcohol. The exhalation of small quantities of wine with food has been already recommended as sometimes useful in stimulating the appetite and assisting digestion, in cases where there are no symptoms of asthenia, but when such symptoms arise, alcohol must be employed in larger quantities. It may be stated generally that a pulse of over 120 or 130 calls for the employment of stimulants. Brandy appears in most cases to answer best. The amount administered must depend upon its effects, and although in most cases from four to eight ounces in the twenty-four hours will be sufficient, if the asthenia persist it must be given in very much larger quantities. Bark and camphor have also been employed as stimulants, and in some cases they are useful in addition to the alcohol.

In the treatment of failure of cardiac power, however, it is important to attempt to modify, as far as possible, those conditions upon which such failure principally depends. The most important of these conditions is the pyrexia (Jurgensen). Various remedies have been employed with the object of diminishing pyrexia. Of these acetate, tartar emetic, and veratrum, although they all have more or less effect in relieving both the frequency of the pulse and the temperature, tend to weaken the heart, and are consequently contraindicated in pneumonia. Digitalis is perhaps less objectionable, but its liability, in the large doses in which it must be administered, to depress the circulation, renders its exhibition somewhat dangerous.

The two remedies which appear to be of most value in reducing the pyrexia of pneumonia are quinine, and the external application of cold.

Quinine has been used more largely in Germany than in this country. It must be given in large doses—thirty grains or more. It is usually best to administer one dose early in the evening and not to repeat this until after an interval of twenty-four hours, and it is often well at the same time to give a full dose of alcohol (brandy, an ounce to an ounce and a half). Quinine thus given undoubtedly in many, although not in all, cases produces a marked reduction in the temperature, and it is desirable to employ it when such a reduction is indicated.

A much more efficient agent in diminishing the pyrexia than quinine is the external application of cold. This mode of treatment also has been much more largely employed abroad than in this country, and here it is only in quite exceptional cases, where the temperature ranges very high (106° or 107° Fahr.) that its employment would be considered justifiable. The following is the method of procedure recommended by Professor Jurgensen.—When the temperature reaches 104° Fahr. the patient should be placed in a bath at a temperature of 60° Fahr., and be kept there from seven to twenty-five minutes—according to the effect on the temperature. The pulse must be carefully watched, and stimulants be administered both before, during, and after the bath. If necessary the temperature of the water must be gradually reduced to 42° Fahr. The cooling process usually continues for about a quarter of an hour after removal from the bath. The bath must be repeated when the temperature again rises to 104° Fahr. Jurgensen recommends this treatment before the superintention of symptoms of cardiac failure, with the object of diminishing the injury to the heart caused by the pyrexia. When there is marked asthenia, and the heart's action is already much weakened, such treatment requires to be employed with great caution, owing to the temporary depression caused by the cold, and the increased work at first thrown on the heart from the contraction of the peripheral blood-vessels. Under these circumstances the propriety of employing it is probably doubtful.

There are other methods by which cold may be applied externally with the object of reducing temperature, namely, by packing the patient in a wet sheet, by the application of ice-lags to the spine, and by sponging the surface of the body with cold water. These, however, are less effectual than the bath, and they often cause more distress to the patient. The effect of such treatment is not only to reduce the bodily temperature, but also the frequency of the pulse and respirations, and it often induces quiet sleep.

Although failure of cardiac power is the chief source of danger in pneumonia, dyspnoea is occasionally a most grave symptom, especially in those cases in which both lungs become involved. This dyspnoea is due partly to the lung-consolidation, and partly to the pyrexia; hence it will be only partially relieved by anything which reduces the temperature. It has long been known that the dyspnoea of pneumonia is diminished temporarily by venesection, and at the present day this is probably the only symptom for the relief of which the practice of bleeding would be considered at all justifiable. In

considering the adriability of removing blood in those cases in which dyspnoea constitutes an urgent symptom, it must, however, be borne in mind not only that the relief is merely temporary, but that the loss of blood must tend more or less to weaken the patient, and hence to favour that condition of asthenia which is of all things the most to be feared. Bleeding is certainly only to be thought of when the dyspnoea threatens life, and when at the same time the strength, as indicated by the pulse, is good, and it should not exceed the removal of eight or ten ounces of blood. Such cases are certainly not common, and when they do occur, it is a question whether it would not be safer practice to endeavour to relieve the dyspnoea by reducing the temperature (either by the cautious application of cold or by quinine), than to have recourse to the lancet.

Of the comphcations delirium sometimes calls for treatment. Active delirium is not common in pneumonia, except in those who have been intemperate. When marked it is always indicative of danger. In its management the practitioner must be guided by the general condition of the patient. It is usually accompanied by asthenia, and hence calls for the exhibition of stimulants. The influence of an experienced nurse is most important. If the pyrexia is considerable, the advisability of wet packing or of the cold bath should be considered. In many cases simply sponging the surface of the body with cold water produces a soothing effect. The application of ice to the head for a short time may also be tried. If these means fail inquieting the patient, and the delirium is very violent and prevents sleep, it may in some cases be advisable to administer an opiate. This should only be done, however, as a last resource, and when there is marked asthenia it is quite inadvisable. The opiate should be given in one full dose sufficient to procure sleep. Morphia administered hypodermically, or given with ammonia or brandy by the mouth, is perhaps the best form of exhibiting it.

Of the management of other complications occurring in the course of pneumonia there is nothing special to be remarked; they must be treated on general principles. The existence of bronchial catarrh often requires small doses of ipecacuanha, ammonia, and salines. Diarrhoea and gastric symptoms are to be met by careful dieting, chalk, bismuth, and, if necessary, other astringent remedies. In pneumonia, as in other acute diseases, the administration of an opiate enema is an efficient and safe means of checking diarrhoea. Pericarditis rarely admits of any special interference.

Convalescence.—During the period which immediately succeeds the crisis, the utmost care is required to support the patient, and to prevent any serious amount of prostration, which at this time sometimes supervenes. Stimulants are usually required for some days after the temperature has attained the normal standard. Convalescence in most cases is quickly established. Solid diet is soon desired, and may be safely given. Tonics—such as quinine, iron, and cod-liver oil—and change of air are useful in assisting the restoration to health.

B Secondary Pneumonia.—**Definition.**—Secondary pneumonia is a local affection, not a general disease. It is an inflammation of the lung occurring in those who are the subjects of some other disease, the pneumonic process standing in more or less causal relation to the disease in the course of which it supervenes.

Intercurrent Pneumonia.—Before proceeding to consider secondary pneumonia as thus defined, it is to be remarked that the general disease—acute pneumonia—occasionally occurs in the course of other diseases as an *accidental* complication, its occurrence not being influenced by the pre-existing condition. Such pneumonias may be termed *intercurrent*, and they are to be distinguished from the local secondary affections. They often closely resemble, in their clinical features, the acute disease as it has been already described, although in some cases they are more or less modified by the disease in the course of which they occur.

Hypostatic Pneumonia.—There is also a class of consolidations of the lung very common in those who are the subjects of other diseases, which are often described as secondary pneumonias but which are really for the most part non-inflammatory in their nature, and will, therefore, be very briefly alluded to in the present article. These are those consolidations so often met with at the bases and more dependent portions of the lungs, in the course of both chronic and acute diseases, and also in the aged and cachectic. They have been termed *hypostatic pneumonias* and consist, in the main, of collapse, hyperemia, and asthma of the lung-tissue, resulting from weak inspiratory power, feeble circulation and gravitation. The consolidation thus mechanically induced is increased by more or less exudation of liquor sanguinis and blood-corpuscles into the alveoli; which exudation is due to the damage to the walls of the capillaries caused by the blood-stasis (Cohnheim). There is also some swelling and proliferation of the alveolar epithelium. The frequent occurrence of this pathological activity in collapsed and oedematous lung-tissue is discussed at greater length under the head of bronchopneumonia.

ETIOLOGY.—Secondary pneumonias, as already stated, bear a causal relation to the disease in the course of which they supervene. They would seem to owe their origin almost exclusively to some abnormal condition which the pre-existing disease has induced. They occur in the course of many diseases, and sometimes appear to constitute the acute affection which determines dissolution. There is one disease in which such pneumonias are especially frequent—namely, Bright's disease. Pneumonia occurring in the course of Bright's disease, however, sometimes closely resembles the acute primary affection, and the Bright's disease is probably merely one of the elements concerned in its causation, but more frequently it is simply the local affection about to be described.

ANATOMICAL CHARACTERS.—The changes occurring in the lung in secondary pneumonia are, for the most part, precisely similar to those of the acute primary disease. In many cases, however, the consolidation is less dense, and

epithelial activity sometimes constitutes a more prominent feature in its production. The pleura is usually implicated, but not so invariably so as in primary pneumonia. When associated with Bright's disease, the consolidation often passes rapidly into the stage of grey hepatization. With regard to the situation of the consolidation, it is more frequently situated in the upper and middle lobes, and is more often double, than is that of the primary disease.

SYMPTOMS.—The clinical phenomena of secondary pneumonia differ from those of the acute primary disease, the symptoms so characteristic of the latter being almost entirely wanting. The symptoms which do exist are often but little pronounced, and the disease may even run an almost latent course. This latency of symptoms is often partly due to their being masked and modified by those of the disease to which the pneumonia is secondary.

The onset of the pneumonic process is usually unattended by rigors or other marked phenomena. Cough, expectoration, pain, and dyspnoea are often slight, and they may even escape observation. If cough be present, the sputa may be free from blood, and simply watery or mucopurulent. The pyrexia is moderate, the temperature often not being more than 100° Fahr. Not unfrequently slightly increased frequency of the respiration, with occasional cough and symptoms of increased illness, are all that exist to indicate that pneumonia has supervened.

DIAGNOSIS.—Owing to the frequent latency of the symptoms of secondary pneumonia, the diagnosis often rests, for the most part, upon the existence of physical signs of pulmonary consolidation. When the consolidation occupies the posterior and inferior portions of the lung, it may be impossible to distinguish it from simple hypostasis. See *HYPOSTASIS*.

PROGNOSIS.—The supervention of pneumonia in the course of a chronic disease usually, but by no means invariably, indicates that the disease will shortly terminate in death. The pulmonary inflammation appears to determine dissolution. Pneumonia occurring in acute diseases materially increases the gravity of the prognosis.

TREATMENT.—The treatment of secondary pneumonia usually resolves itself into that of the disease in the course of which it occurs. Warm applications to the chest, small doses of ammonia, and alcoholic stimulants may sometimes favourably influence the pneumonic process.

C Broncho-Pneumonia.—*SYNON.* Catarrhal inflammation of the lungs, Lobular pneumonia, Fr *Pneumonie lobulaire*, *Broncho-pneumonie*, Ger *Bronchopneumonie*.

DEFINITION.—Bronch-, catarrh, or lobular pneumonia is inflammation of the lung-tissue associated with and usually secondary to, inflammation of the bronchial mucous membrane. In the earlier stage the pulmonary inflammation is commonly limited to scattered groups of air-vesicles, hence the term *lobular* which is applied to this form of pneumonia. As the process advances, the inflammatory nodules may gradually coalesce so as to produce larger tracts of consol-

idation. The inflammatory products which fill the alveoli consist principally of cells, derived from the epithelium of the alveoli, and from the bronchial mucous membrane; exudation and emigration play a much less prominent part in the process than they do in acute pneumonia. Owing to this preponderance of epithelial products, and to the association of the pulmonary with the bronchial inflammation, the process is also known as *catarrhal pneumonia*.

ETIOLOGY.—Broncho-pneumonia, as already stated, is invariably associated with bronchial catarrh. In some cases it would appear that the injury which produces the bronchial inflammation produces at the same time inflammation of the alveolar walls, but much more frequently the bronchitis precedes the pneumonia, and gives rise to it in a manner to be hereafter described. Whatever causes inflammation of the bronchial mucous membrane may thus be a cause of broncho-pneumonia.

Bronchitis is frequently followed by broncho-pneumonia, especially in childhood and in old age. All those conditions which favour the occurrence of bronchitis must therefore be enumerated amongst the causes of this form of pneumonia. Of these conditions it will be sufficient to mention here the marked influence of cold and damp and, to a less extent, of heart-disease and emphysema, also the inhalation of irritating gases, and of an atmosphere containing irritating particles of solid matter.

It is the bronchitis associated with certain infectious diseases which is most liable to be followed by broncho-pneumonia. This is especially the case with that accompanying measles and whooping-cough. In both these diseases this form of lung-complication is exceedingly frequent. It also sometimes occurs in connexion with the French distemper of infants and diphtheria.

All conditions which tend to impair the general health favour the occurrence of broncho-pneumonia. The weakly and debilitated suffer most. Bad air and insufficient food are most important predisposing causes. A state of malnutrition not only renders the bronchial mucous membrane abnormally liable to become inflamed, but also diminishes the power of the respiratory muscles, and thus aids in the production of pulmonary collapse, a condition which, as will be seen presently, is especially favourable to the pneumonic process. Owing to the general debility and weakness of the thoracic parietes in rickets, bronchitis in the subjects of this disease is exceedingly liable to be followed by broncho-pneumonia.

Broncho-pneumonia is most common during the first four years of life—the period when bronchial catarrh, measles, and whooping-cough are so frequent. It is also common in old age. In young adults it is comparatively rare. Sex has no influence.

ANATOMICAL CHARACTERS.—The appearances presented by the lungs after death vary. The bronchi always exhibit signs of more or less bronchial catarrh. This may involve the whole of the bronchial mucous membrane, but it is usually most marked in the smaller tubes. These are found containing a thick, tenacious, and often

puriform secretion, which is occasionally here and there drier or inspissated. The mucous membrane of these tubes is more or less softened, swollen, red, and thickened, and often presents irregular superficial erosions. Owing to this inflammatory swelling the tubes stand out prominently on section of the lung. Cylindrical dilatactions of the tubes are also frequently met with.

The lung-tissue itself exhibits, associated in various degrees, collapse, congestion, oedema, emphysema, and pneumonic consolidation. The bluish, non-crepitant, depressed portions of collapse, which become darker and more friable with age, are usually most abundant in the lower lobes and margins of the lungs. The collapse sometimes involves the whole of one lobe, but more commonly it is limited to much smaller areas of the lung. When scattered and limited in its distribution, there is usually more or less emphysema of the intervening portions of the lung; when very extensive in the lower lobes, the emphysema is most marked in the upper.

Those portions of the lung in which the pneumonic process has supervened most commonly appear as scattered nodules of consolidation, varying in size from a small pea to a hazel nut. These are ill-defined and pass insensibly into the surrounding tissue, which is variously altered by congestion, collapse, and emphysema. They are of a reddish-grey colour, slightly elevated, smooth, or very faintly granular, and soft and friable in consistence. As they increase in size they may become confluent, and thus are produced larger tracts of consolidation. In a more advanced stage, the nodular and more diffuse consolidation becomes paler, firmer, and drier, and somewhat resembles in colour the greyish-yellow hepatization of acute pneumonia. The cut ends of dilated bronchi, filled with pus, are occasionally seen in the centres of the pneumonic nodules.

Microscopical characters.—When examined microscopically this consolidation is seen to consist of an accumulation within the alveoli of a gelatinous mucoid-looking substance, small cells resembling leucocytes, and epithelial elements. In many cases much of this accumulation is precisely similar to that contained in the smaller bronchi; and it is evidently the inflammatory and richly cellular bronchial secretion which has been inhaled. At the same time it is in the highest degree probable that it is partly the result of exudation and emigration from the pulmonary capillaries, such exudation and emigration, however, do not play nearly such a prominent part in the process as they do in acute pneumonia, and a fibrinous coagulum is rarely met with. Associated with this material are large epithelial elements, probably the offspring of the alveolar epithelium. These vary considerably in number. In some portions of the consolidation they may be very few, whilst in others they may constitute the predominant change. These differences probably depend upon how far the inhalation of the bronchial secretion constitutes a part of the process. The epithelium covering the alveolar walls is more or less swollen and granular, and is often loosened from its attachment.

Many of the nodules of consolidation met with in the lungs after death from broncho-pneumonia, differ somewhat from those which have been described. They are smaller and softer, of a more yellow colour, less prominent, and less granular; and on scraping, a puriform liquid is obtained from them. These consist almost exclusively of puriform secretion inhaled from the bronchi, and there is an almost complete absence of epithelial elements, and of other evidence of alveolar inflammation. Some of these nodules are merely the cut ends of dilated bronchi filled with pus.

The pleura is usually more or less injected, and a little lymph with small cellophaneous are commonly met with. These appearances are most marked in the vicinity of the sub-pleural pneumonic nodules.

The subsequent changes which take place in the lungs vary. When the disease does not end in death, resolution is the most common termination. The contents of the alveoli undergo fatty degeneration, and are removed by expectoration and absorption, the lung gradually regaining its normal characters. This process, however, is less readily effected than in the consolidation of acute pneumonia, and it often occupies such a lengthened period that some thickening of the bronchial and alveolar walls, and dilatation of the smaller bronchi remain. In still more chronic cases the fibroid thickening is much more marked, and considerable irregularly distributed pigmented induration and bronchial dilatation may be produced (see Chronic Pneumonia). In these chronic forms the contents of the alveoli sometimes caseate, and the caseous products and thickened alveoli may in exceptional cases, disintegrate, and thus lead to the destruction of the lung. Such a result comes under the category of phthisis, and will therefore not be described in the present article.

Pathology.—The inflammation of the bronchial mucous membrane, which is invariably associated with broncho-pneumonia, in the great majority of cases precedes and is the principal cause of the pneumonic process. In exceptional cases it would appear probable that the same injury which produces the bronchial inflammation produces at the same time the inflammation of the air-vesicles. Inflammation of the bronchial mucous membrane may give rise to broncho-pneumonia in two ways:—(1) By causing, in the first place, collapse of the lung-tissue, and (2) by the direct extension of the inflammation from the bronchi to the air-vesicles. The pneumonic process being the result of the bronchitis almost invariably involves simultaneously both lungs.

1 *Broncho-pneumonia consecutive to collapse*. Collapse of the lung-tissue greatly favours the occurrence of broncho-pneumonia, and usually the pneumonic process is principally confined to those portions of the lung in which collapse has taken place. This is particularly the case in young children. Although it would be beyond the scope of the present article to discuss at length the relation which subsists between bronchial catarrh and pulmonary collapse, the mode of production of the latter may be briefly indicated. There are two circumstances principally concerned in the production of the collapse

which is consecutive to bronchitis—the narrowing of the bronchial tubes, and the weakness of the inspiratory power. The mucous membrane of the bronchi becomes considerably swollen as the result of the inflammatory process, often being thrown into folds, and its surface is covered with thick tenacious mucus. These conditions may cause so much narrowing of the smaller tubes as to render the entrance of air exceedingly difficult, and they may even completely prevent it. In addition to this bronchial narrowing the power of inflating the lungs is usually diminished. This is due partly to the general debility which so often exists prior to the bronchitis, and partly to the damage to the respiratory muscles caused by the febrile process. The superficial character of the respiration due to the fever also aids in the production of the collapse, as does also any weakness of the osseous structures of the thorax, such as exists in rickets. The collapse thus induced is especially frequent in the posterior and inferior portions of the lungs—those portions in which normally the inflation of the lung is the least complete. Commencing here the process may gradually extend upwards till large areas of both lungs become involved. In other cases, owing to a more irregular distribution of the bronchial obstruction, the collapse is limited to small isolated portions of the lung. These portions vary in size from a hemp-seed to a walnut. They are commonly more or less wedge-shaped, with their apices towards the bronchus leading to the group of collapsed lobules, and the lung-tissue around them usually presents various degrees of congestion and emphysema.

The tendency of the pneumonic process to occur in the collapsed portions of the lung is due partly to the hyperæmia which is induced by the collapse, and partly to the irritation of inhaled bronchial secretion. Collapse of the lung-tissue invariably induces more or less congestion. This is owing to the absence of the expansion and contraction of the air-vesicles, which normally aid the pulmonary circulation, and also to the impediment to the blood-flow resulting from imperfect aeration. This congestion is quickly followed by œdema, and the bluish-purple collapsed portions of the lung become deeper in colour, less resistant, and more friable in consistence. In lung-tissue thus altered an inflammatory process, characterised partly by exudation and partly by epithelial activity, is prone to supervene.

Another circumstance which often appears to play a prominent part in the causation of the pneumonic process, is the presence within the alveoli of the inflammatory products of the bronchial mucous membrane. Such products are frequently found in the lungs in cases of broncho-pneumonia. They occur in scattered groups of air-vesicles, and are evidently inhaled. They are found both in the air-containing and in the collapsed portions of the lung, but especially in the latter, the presence of collapse necessarily interfering with their removal by expectoration or absorption. These inhaled products are often found filling small groups of alveoli without any evidence of subsequent inflammation, and there can be no doubt that many of the patches of conglu-

dation which are usually described as pneumonic are in reality non-inflammatory in their nature, and are thus produced. At the same time, owing to the irritation of the inhaled secretion, it tends to induce inflammatory changes within the alveoli, and these changes are frequently largely owing to its presence. Jürgensen accounts for the pneumonic process occurring in isolated spots in the collapsed lung by regarding the inflammation as being determined by the inhaled bronchial secretion.

2. Broncho-pneumonia independent of collapse. Although the pneumonic process is usually consecutive to collapse it may occur independently. This may be owing either to the direct extension of the inflammation from the bronchi to the air-vesicles, or to the influence of inflammatory products inhaled from the bronchi. In other cases it is possible that the injury which causes the bronchitis causes at the same time the inflammation of the pulmonary alveoli.

SYMPTOMS. The symptoms of broncho-pneumonia are, to a great extent, those of capillary bronchitis. They vary according to the severity of the bronchitis and according as this is associated or not with other disease. In the severe forms of capillary bronchitis of childhood, and in that associated with measles, the implication of the lung usually gives rise to early and marked symptoms, and the disease runs a comparatively acute course. In the less severe forms of bronchial catarrh, on the other hand, and in that associated with whooping-cough, the supervention of a pneumonic process commonly occurs later, the symptoms are less pronounced; and the course of the disease is much more chronic. Although various gradations are met with between these more acute and the chronic forms, it will be advisable, for the sake of description, to consider them separately.

Acute broncho-pneumonia.—The more acute forms of broncho-pneumonia occur especially as a complication of measles, and in the simple capillary bronchitis of childhood. In measles the pneumonic process commonly supervenes towards the end of the first, or beginning of the second week, but it may be much later.

The early symptoms are those of severe catarrh of the smaller bronchi—pyrexia, frequent cough, accelerated respiration, slight action of the nares, &c. Such symptoms precede, for a varying length of time, those due to the implication of the lung-tissue. The earliest symptoms of the pneumonic process are by no means well-defined, and consequently the time at which the lung becomes involved cannot be fixed with certainty. Rigors and vomiting are but rarely observed.

Usually an increase in the acceleration of the respiration, or in the dyspnoea, are the first signs of the pulmonary implication. The breathing becomes very rapid, and commonly causes much distress, the child tossing about and being exceedingly restless. This dyspnoea is more marked at some times than at others, and is occasionally more or less distinctly paroxysmal. The respiration is superficial, inspiration being short, and the expansion of the thorax imperfect. There is marked action of the accessory respiratory muscles, and the upper portions of

the thorax are raised, whilst the lower are retracted during the inspiratory act; the action of the aures is very pronounced.

An increase in the pyrexia which attended the pre-existing bronchitis is, with few exceptions, observed as the lungs become involved, and such increase is to be regarded as one of the most valuable indications of the existence of a pneumonic process. The maximum temperature of acute simple bronchitis is seldom higher than 102° Fahr., whereas that of the secondary pneumonic process is often 104° or 105° . This increase usually occurs more or less gradually, —there is rarely the sudden rise of temperature met with in acute pneumonia. Unlike the temperature of this disease also, the fever of broncho-pneumonia runs no definite course. It varies with the extent of the lung-implication, and with the rapidity with which this implication is effected. There is no regular diurnal variation, the remissions and exacerbations are often considerable; and they occur at irregular times, the temperature being sometimes higher in the morning than at night. The cough, which before the implication of the lung was paroxysmal in character, gradually becomes less and less so, and it now often causes much pain to the patient. The sputa are bronchitic in character, usually very tenacious, and occasionally streaked with blood; as, however, expectoration rarely occurs in the child, they are not often seen. The pulse is much increased in frequency, in children under five years often being 150. It may in the earliest stage of the disease be moderately full and strong, but it quickly becomes soft, small, and feeble. In addition to the above, there are often symptoms referable to the digestive organs. Of these diarrhoea is the most important. This is quite frequent, especially when the disease follows measles. It is very readily induced by medicines and by improper feeding, and as it greatly weakens the patient, it is important that this liability to it should be kept in mind. Vomiting, as already stated, is very rare as an initial symptom; it is, however, common in the course of the disease, especially as a result of cough, the bronchial secretion, together with the contents of the stomach, often being expelled.

As the implication of the lungs increases, the breathing becomes still more rapid and superficial; the dyspnoea is more marked, the expression is anxious; the face is pale; and symptoms of carbonic-acid-poisoning become evident. Strength now fails; the face and lips become cyanotic; and the extreme restlessness gives place to apathy and a semi-comatose condition, which is interrupted from time to time by ineffectual efforts to cough. With the rapid failure of strength and increasing cyanosis, cough almost ceases; the pulse becomes exceedingly feeble; and the child, often extremely emaciated, may die exhausted, and in a condition of more or less profound coma. Sometimes death occurs suddenly during a paroxysm of cough, or with convulsions.

Chronic broncho-pneumonia.—The symptoms of the more chronic forms of broncho-pneumonia, such as occur especially after whooping-cough, and also after bronchial catarrh of moderate severity, differ somewhat from those of

the acute disease. The pneumonic process commonly supervenes later, and the course of the disease is much more protracted. As in the acute form, pyrexia and increased frequency of respiration are the earliest indications of the pulmonary implication. In these cases, however, there is usually but little if any fever prior to the pneumonia, it comes on very gradually; and the maximum temperature is much lower than in the more acute form, commonly not being more than 102° Fahr. The course of the pyrexia also is still more irregular, lengthened periods of very slight fever being interrupted from time to time by slight exacerbations. Loss of appetite, great emaciation, increasing difficulty of breathing, and loss of strength, characterize the disease. Such symptoms may continue for months, and the child ultimately die, or recover with more or less damaged lungs.

When broncho-pneumonia occurs in adults and in the aged, the symptoms are for the most part much less pronounced than in the child. In strong adults the disease is perhaps most common after diphtheria, and here the pulmonary symptoms may be well-marked, but in the debilitated, and especially in the old, the course of the disease is much more latent, very slight pyrexia (100° Fahr.), slight cough and dyspnoea, and marked debility being the principal symptoms observable.

In the aged and feeble, broncho-pneumonia is very frequently associated with that form of lung-consolidation which results from weak inspiratory power, feeble circulation, and gravitation (hypostatic pneumonia). It has already been stated that this consolidation, which consists mainly of collapse, hyperaemia, and oedema of the lung-tissue, favours a catarrh and proliferation of the alveolar epithelium. Hypostatic consolidation may exist quite independently of bronchial catarrh, but when such catarrh occurs in the aged and feeble, gravitation often determines the supervention of the pneumonic process, which under such circumstances is consequently not infrequently unilateral.

When the more acute varieties of broncho-pneumonia terminate fatally, they usually do so from the tenth to the fourteenth day of the disease. Death, unlike that from acute pneumonia, is mainly due to the interference with the respiratory function and, to a much less extent, to failure of cardiac power (Juergensen). The interference with the respiration is much greater than in acute pneumonia, for, in addition to the diminution of the respiratory area, due to the pulmonary consolidation and collapse, there is the much more important cause of interference—namely, the impediment to the entrance of air, caused by the swelling of the bronchial mucous membrane, and the accumulation of secretion in the bronchial tubes. These interferences with respiration necessitate increased action of the respiratory muscles, but with the progress of the disease these muscles become weakened, partly by the fever, and partly from the imperfect supply of oxygen. With this failure of respiratory power the incompleteness of oxygenation necessarily increases, until the supply of oxygen may become so small as to lead

to complete muscular paralysis. The damage to the heart, as in acute pneumonia, is due partly to the diminished respiratory area, and partly to the fever, but this damage is a much less important element in the causation of dissolution in broncho-pneumonia, than it is in the general disease (Jürgensen). In chronic broncho-pneumonia death may not occur for some months, and then it results as much from general failure of strength as from interference with the respiratory function.

When the disease does not terminate in death, improvement in the symptoms is always gradual. The temperature falls slowly, several days, and occasionally some weeks, being occupied in the completion of defervescence, and this gradual decline is usually interrupted by more or less marked and frequent exacerbations and remissions of the fever. The cough and dyspnoea diminish, and the appetite gradually returns, but restoration to health is always protracted, and the child remains for some time especially liable to repetition of the bronchial symptoms.

Sometimes recovery from the broncho-pneumonia is not complete, and the disease leads to induration of the lung, dilatation of the bronchi, &c. (see Chronic Pneumonia). Emphysema and acute tuberculosis are occasional sequelae. That the disease sometimes terminates in phthisis, especially in children and in those who inherit weak lungs, appears to the writer to be indisputable.

Physical signs.—The physical signs of broncho-pneumonia are in the main those of capillary bronchitis. Imperfect expansion of the thorax, elevation of the upper portions and recession of the lower, during the inspiratory act, moist and dry *râles*, audible over both sides, and the absence of any marked alterations in percussion-resonance, are the principal signs observable, not only in the earlier stages, but throughout the whole course of the disease. The recession of the chest-wall is increased by collapse. The imperviousness of the pulmonary implication is indicated rather by the symptoms—increased in the pyrexia and in the dyspnoea—than by any marked alteration in the physical signs. The difficulty of detecting the lung-consolidation is due to its usually being limited, in the earlier stages, at all events, to small areas, which are surrounded by healthy or emphysematous lung, so that resonance on percussion is but little impaired. It is only when these small areas have coalesced into larger areas of consolidation, that any marked alterations in percussion-resonance are discoverable. The impaired resonance due to collapse is not to be distinguished from that due to pneumonia consolidation, and, inasmuch as the collapse is so often symmetrical, involving both bases posteriorly, the difficulty of appreciating it is increased. Much more valuable aid in physical diagnosis is in most cases to be obtained from auscultation. Over those portions of the lung where consolidation has taken place the most bronchitic *râles* tend to assume a somewhat metallic quality, they also become finer, though not so fine as true pneumonic crepitation; and they are more superficial. The detection of these superficial, somewhat metallic fine moist *râles*, heard with inspiration, and often with

expiration, over small areas of the lungs, is a most valuable and often the only physical sign of the pulmonary implication. If large areas become consolidated, there is, in addition to this, some impairment of resonance on percussion.

Complications.—These are few. It is scarcely necessary again to state that bronchial catarrh is always present. Pleurisy is less common than in acute pneumonia. Slight inflammation of the pleura is, however, usually found *post mortem*, over those portions of the lung which are consolidated. Pleuritic effusion is rare. Intestinal catarrh is a very important and common complication. The liability to this in the child, and the mechanical congestion resulting from the obstructed pulmonary circulation, must be borne in mind in explaining its frequency.

Convulsions occasionally occur, and are of unfavourable augury. The nervous phenomena in some few cases have been described as simulating those of tubercular meningitis. Catarrhal laryngitis, associated with much spasm and laryngeal stenosis, is sometimes observed, especially after measles.

Diagnosis.—The diagnosis of broncho-pneumonia is occasionally difficult. This difficulty is mainly owing to the co-existence of capillary bronchitis. The recognition of the pulmonary implication in its earlier stages is often impossible. The increase in the pyrexia, and in the frequency of respiration, are the symptoms of the most diagnostic value. Owing to the small areas of lung involved, any alteration in the physical signs of the capillary bronchitis may be entirely wanting. The occurrence of extensive collapse in the earlier stages gives more marked physical signs of consolidation, and hence renders the diagnosis more easy. It is almost impossible to diagnose correctly, either by symptoms or by physical signs, between the collapse and the pneumonia consolidation. This, however, is of but little practical importance, inasmuch as the collapse is usually associated with, and often the immediate precursor of, the pneumonic process.

The diagnosis of broncho-pneumonia from the pulmonary consolidation of acute pneumonia may occasionally be difficult in the later stages of the former, when an extensive area of the lung has become consolidated. The history of the case, and especially the course of the pyrexia, will usually suffice to distinguish them.

The distinction from acute tuberculosis sometimes presents much difficulty, as does also the recognition of tuberculosis and phthisis as an occasional result of the disease. A careful consideration of the earlier symptoms, and the existence or not of marked predisposition, are here most important. Slight and irregular pyrexia, existing before the superposition of lung-symptoms, is greatly in favour of tuberculosis. In some cases, however, the phenomena of these diseases are so analogous that a certain diagnosis is impossible.

Prognosis.—Broncho-pneumonia is much more dangerous than the acute primary disease, and the mortality from it is much greater. The more chronic forms are more fatal than the acute. The two circumstances which have an especial influence upon prognosis are the age of

the patient, and the general health. Before puberty, the younger the patient the graver the prognosis. In children under five years, the mortality is exceedingly great (probably about 20 per cent.) The disease is also especially fatal in weakly children, and in all those who are constitutionally feeble, or debilitated by previous illness. The existence of rickets materially increases the gravity of prognosis. The danger also increases greatly with the extent of lung involved, much more so than is the case in acute pneumonia. Of the value of the several symptoms as influencing prognosis, after the description which has been given of the disease and of the modes in which it tends to cause death, it is hardly necessary to speak further. Symptoms of imperfect aëration of the blood are those most to be feared.

TREATMENT.—In the treatment of bronchopneumonia, it is important to bear in mind—1st, that the disease is invariably associated with, and is in the main induced by bronchial catarrh, and by its so frequently attendant collapse; 2ndly, that its occurrence is especially favoured by everything that weakens the patient, and 3rdly, that it tends to destroy life principally by interfering with the function of respiration, which interference necessarily increases with the consequent weakening of the respiratory power. Such being the facts, it is obvious that the main object of treatment will be, first, to control bronchial catarrh, and endeavour so to modify it as to prevent the occurrence of collapse; and, secondly, to support as much as possible the strength of the patient, with the object of preventing not only collapse, but also that increased interference with the function of respiration which results from weakening of the respiratory muscles.

It would be out of place in the present article to enter into a detailed description of the management of acute bronchitis (*see* BRONCHITIS, Diseases of). It will be sufficient to indicate the more important means of controlling the disease, with especial reference to the prevention of the so frequently attendant collapse.

The patient should be kept in a warm room, the temperature of which should never be allowed to fall below 60° Fahr. The room should be well, but carefully ventilated, and protection from draughts is important, much more so than in the treatment of acute pneumonia. It is also advisable to keep the air moist by means of a steam kettle, as the exhalation of water from the lungs is thus diminished, and the bronchial secretion consequently rendered less tenacious, and more easily removed by cough. The diet, which must be regulated according to the age of the patient, should be nutritious and easily digestible, the importance of supporting the strength being kept in mind. When the disease follows measles, the liability to gastro-intestinal catarrh must not be forgotten. Small doses of ipecacuanha with saline should be administered frequently. The chest should be enveloped in lightly made linseed and mustard poultices; or, what in the case of very young children answers better, it should be rubbed three or four times daily with some stimulating liniment, and kept wrapped in cotton-

wool covered with oil-silk. When the secretion in the tubes is abundant, its removal may be much aided by small doses of carbonate of ammonia. This may be either combined with the ipecacuanha and saline mixture, or given separately in a little milk. Sen-ga, as an infusion, and chloride of ammonium may also be given with the same object. The last-named drug appears to have the effect not only of rendering the secretion less tenacious and more easily removable, but also of diminishing its formation. An occasional emetic dose of ipecacuanha often materially relieves the patient, when numerous *râles* audible over the chest, and increased dyspnoea, indicate an accumulation of the secretion. This, however, must not be given when there is marked exhaustion present. The exhibition of opiates is as a rule contraindicated. When the cough is feeble, and the secretion abundant, they do much harm. In the more chronic forms of the disease, however, and especially when following whooping-cough, where the cough is often violent, and there is but little bronchial secretion, opiates may be cautiously given with advantage, as may also bromide of ammonium.

With the object of reducing the temperature, and also of increasing the expansion of the lungs much may be done by the external application of cold. This method of treatment appears to be especially valuable in increasing the depth and force of respiration, and thus in preventing the occurrence of collapse. Its utility has been strongly advocated by both Bartels and Ziemssen. The method recommended by these physicians consists in the application of cold wet compresses round the chest, which treatment may be continued from half to three or four hours. It is often necessary to repeat the application at intervals for some days, as the beneficial effect is only temporary. This treatment produces a marked reduction of the temperature, and also a diminution in the frequency, but an increase in the depth, of the respirations, the distress being thus considerably relieved, and the patient often falling into a sound sleep. Owing to the depression produced by the cold if too long continued, its effects require to be watched, and when symptoms of exhaustion appear, the cold should be discontinued, to be renewed again subsequently.

Another method of treatment by cold is that recommended by Juergensen, and considered by him very preferable to the preceding, as being more effectual and causing less discomfort. This is a treatment by baths and cold affusion. The child is first placed in a bath at a temperature of 77° to 86° Fahr. for twenty minutes; and then from 10 to 20 quarts of water at 36° Fahr. are to be quickly thrown over the back and chest. This causes several deep respirations, and thus is valuable in preventing collapse; but it appears to have less effect in reducing temperature than the treatment by cold compresses.

Whilst these various means are being employed, it is all-important to support the strength of the patient. Brandy is here most valuable, and it is to be remembered that children bear stimulation well. The brandy is

best given in milk, the quantity being proportioned to the age of the patient. An infant may begin with from five to ten drops every two or three hours. Under its influence the pulse usually improves, the respirations become less frequent, and the distress and evanescence diminish. The administration of brandy is usually advisable before and during the treatment by cold. When prostration is extreme, or deglutition difficult, both the brandy and other nutriment may be administered by the rectum.

In the chronic forms of broncho-pneumonia these more active methods of treatment are but rarely called for. Here attention to nutrition is most important, and small doses of cod-liver oil in the later stages, even before the complete disappearance of the pyrexia, are often useful. When the disease leads to induration of the lungs and dilatation of the bronchi, the treatment resolves itself into that of chronic pneumonia.

Convalescence, it must be remembered, is always slow, and there is a tendency to relapse. Great care is consequently requisite during this period. All causes of catarrh must be carefully guarded against, and the restoration to health assisted by nutritious diet, cod-liver oil, and iron. A change of air is especially valuable.

1) Chronic Pneumonia.—*Saxon* Chronic Inflammation of the Lungs, Cirrhosis of the Lung; *Fr.* *Pneumonie interstielle*, *Ger.* *Lungen-cirrhose*.

Definition.—Chronic pneumonia is a comparatively rare disease, characterised by a gradual increase in the connective tissue of the lung which leads to an induration of the pulmonary texture, and to progressive obliteration of the alveolar cavities. It is commonly associated with catarrh and dilatation of the bronchi, and often with ulceration of the bronchial walls, and excavation of the indurated lung. Cough, expectoration—often abundant, but varying with the bronchial catarrh—dyspnoea, gradual impairment of nutrition, and occasional accessions of slight pyrexia, are the most prominent clinical phenomena accompanying the disease, which runs an exceedingly chronic course—often subject to long periods of quiescence, but tending to terminate fatally in from five to fifteen years.

Chronic pneumonia is also known as *interstitial pneumonia*. In its most marked form it constitutes the disease which received from *Corgan* the name of *cirrhosis*. The term 'fibroid phthisis,' which is sometimes applied to it, is altogether inapplicable.

Ætiology and Pathology.—It is exceedingly doubtful if chronic pneumonia is ever a primary and independent disease. It probably in all cases owes its origin to some antecedent inflammation of the pulmonary or bronchial textures, or of the pleura. It may be stated generally that all inflammatory processes in the lungs, as in other organs, which become chronic, lead to an increase of the connective-tissue elements, and consequently to fibroid induration of the organ. In the lungs by far the most common cause of such induration is pulmonary phthisis. In all cases of phthisis, excepting those which are the most acute, there is more or less fibroid growth, and the extent of this

growth is, for the most part, in direct proportion to the chronicity of the disease. Those forms of phthisis which are the most chronic, and in which the fibrosis reaches its maximum, have been termed 'fibroid phthisis.' The most chronic cases of phthisis are, it must be admitted, somewhat closely allied to some forms of chronic pneumonia. The two diseases, however, differ pathologically in this respect—that whereas much of the pulmonary consolidation of phthisis tends to undergo molecular death and disintegration, that of chronic pneumonia exhibits no such tendency; but any destruction and excavation of the indurated lung which may take place, is due to secondary inflammation and ulceration commencing in the bronchial walls. In considering the pathology of chronic pneumonia, therefore, it is necessary to exclude in the first place the pulmonary induration of phthisis. Chronic pneumonia must also be separated from that form of pulmonary induration which is produced by long-continued mechanical congestion, namely, brown induration; and from those more localised indurations due to bronchitis, peri-bronchitis, old infarctions, and syphilis.

There appear to be four conditions which may give rise to chronic pneumonia, namely:—1. *Acute pneumonia*, 2. *Broncho-pneumonia*, 3. *Pleurisy*, 4. *The inhalation of irritating particles of solid matter*. Each of these must be considered separately.

1. *Acute pneumonia*.—Chronic pneumonia is an occasional, though quite rare result of the acute primary disease. The pulmonary consolidation of acute pneumonia almost invariably undergoes complete resolution. This resolution is usually effected rapidly, in from seven to fourteen days. Occasionally, however, the course of the disease is more protracted and the consolidation persists beyond the third week. When thus protracted, the hepatised lung tends to become slightly indurated, owing mainly to thickening of the walls of the alveoli. This indurated hepatisation differs but little in its physical characters from ordinary red and grey hepatisation; it is simply somewhat firmer and more resistant. In very exceptional cases this small amount of induration commencing in the alveolar walls may gradually increase so as ultimately to give rise to that extensive fibrosis of the lung which constitutes what is known as chronic pneumonia.

2. *Broncho-pneumonia*.—Broncho-pneumonia appears to be a somewhat more frequent cause of the disease than the preceding (Wilson Fox). The greater liability of this form of pneumonia to lead to pulmonary induration is to be accounted for partly by its longer duration and greater tendency to become chronic, and partly by the existence of bronchial dilatation with which it is so frequently associated. That bronchial dilatation is favourable to an indurative pneumonic process has been especially insisted upon by Dr. Wilson Fox. Dilatation of the bronchi is exceedingly common in the simple bronchitis of childhood, and especially in that associated with whooping-cough and measles; it is also a direct result of pulmonary fibrosis. In whatever way originating, its existence favours the persistence of the catarrhal and pneumonic processes. The removal

of secretion is rendered more difficult; the retained secretion tends to increase and keep up the irritative process, both in the dilated bronchi and also in the pulmonary alveoli; and this persistence of the bronchial and pulmonary inflammation leads to fibroid thickening of the bronchial and alveolar walls. In this way more or less disseminated patches of indurative consolidation are produced, which as the process proceeds gradually increase, so that ultimately they may involve large areas of the lung. The progressive tendency of the process is probably partly to be explained by the fact, already stated, that pulmonary fibrosis is a cause of bronchial dilatation, so that fibrosis once established, by inducing further dilatation of the bronchi, favours the extension of the bronchial and pulmonary inflammation.

3. *Pleurisy*.—Pleurisy in very exceptional cases leads to the development of a chronic pneumonia. It appears to be in those cases of pleurisy which are more or less chronic, and in which the lung remains long collapsed from the effusion, that such a result is most liable to occur. The induration of the lung thus induced is often, however, exceedingly partial, consisting merely in some increase of the interlobular connective tissue originating and extending inwards as dense bands from the thickened visceral pleura. In other cases pleurisy probably gives rise to a much more general fibrosis.

4. *Inhalation*.—The inhalation of irritating particles, such as occurs in the trades of miners, potters, stone-masons, grinders, &c., is the cause of the fibrosis of the lungs common amongst persons so employed. The continuous irritation of the inhaled particles induces a bronchial and alveolar inflammation, and ultimately fibrous growth in the bronchial and alveolar walls, which, gradually extending, may involve large areas or even the whole of the lungs.

ANATOMICAL CHARACTERS.—The histological changes met with in the lungs in chronic pneumonia may be described generally as consisting in the development of a fibro-nucleated tissue from the walls of the alveoli, from those of the bronchi, and from the interlobular connective tissue; which new growth, as it increases, and from its tendency to contract, gradually replaces and obliterates the alveolar structure. The character of these changes, however, varies somewhat according to the inflammatory antecedents in which they originate. When chronic pneumonia is the result of acute pneumonia, the principal change takes place in the walls of the alveoli. These become thickened by the growth of a small-celled tissue, in which, associated with the spheroidal cellular elements, there are sometimes elongated fusiform cells, such as are found in embryonic tissue which is in process of forming a fibrous structure. This new growth, in its earlier stages, usually contains new blood-vessels; but later the tissue contracts, and the vessels become to a great extent obliterated. The growth differs from the non-vascular growth of phthisis, inasmuch as it has but little tendency to undergo molecular death and disintegration. The alveolar cavities, where not obliterated, are either empty, or contain exudation-products and a few epithelial cells.

When secondary to ordinary broncho-pneumonia, or to that induced by the inhalation of irritating particles, the new fibroid growth also originates principally from the alveolar walls. Here, however, the growth in the earlier stages is less uniform, and the peri-bronchial and interlobular connective tissues play a more prominent part in the process. The new peri-bronchial tissue invades the walls of the adjacent alveoli, and materially increases the fibrosis.

In the chronic pneumonia resulting from pleurisy, the change as already stated, is often more localised, consisting in the development of dense fibrous bands passing inwards from the thickened pleura. These are developed from the interlobular tissue. In other cases the fibrosis is more general.

In whichever of the pulmonary structures the new fibroid growth originates, as it increases, all the connective tissue of the lung may become involved, and the alveolar cavities be completely obliterated. The new growth, like that met with in the inflammatory indurations of other organs, although in the earlier stages of its development it may be richly cellular and contain new blood-vessels, tends gradually to become less cellular denser, and more contractile. In its more advanced state it often consists either of closely packed wavy fibres, or more frequently of a dense homogeneous or obscurely fibrillated material, associated with which are a few small round or fusiform cells. Sometimes the new growth is found richly cellular, even in the most advanced stages of the disease.

The macroscopical appearances of the lung vary with the extent of the fibroid change. In the earliest stages of the induration resulting from acute pneumonia, where there is merely a slight thickening of the walls of the alveoli, the consolidation very much resembles that of red or grey hepatisation. It differs in being firmer and less friable in consistence, and is somewhat less granular. In the later stages and in all cases where the fibrosis is extensive and general, the lung is diminished in size, dense firm, fibrous, and even cartilaginous in consistence. The cut surface is smooth; and the large amount of irregularly distributed black-pigment usually present, gives to it a peculiar grey, mottled appearance. Numerous dilated bronchi traverse it in all directions.

When the disease is secondary to broncho-pneumonia the fibrosis in the earlier stages is much less general, as it usually is also when the result of pleurisy. Sometimes dense tracts of fibrous tissue are found intersecting the lung in various directions. As the disease advances, however, a large area, or even the whole lung, may become involved.

The bronchi are almost invariably found dilated in those portions of the lung where the induration is advanced. In some cases some dilatation of the tubes is observed in parts which are not involved in the induration. This dilatation is often very considerable and the dilated tubes sometimes form large cavities, which may occupy a large portion of the indurated lung. The walls of the tubes are much thickened, and the mucous membrane is often ulcerated. This secondary inflammation and

ulceration of the bronchi occurs especially in the dilated portions, and it appears here to be induced by the irritation of the retained and putrid secretion. It may extend into and involve the indurated lung and so lead to more or less excoriation. The mucous membrane sometimes sloughs, and the gangrenous process may involve the lung. The large cavities so common in these lungs are in the main, however, dilated bronchi. See *Bronchitis* Diseases of.

The pleura of the affected lung, except in the earliest stages of the disease, is much thickened and adherent.

Site.—Chronic pneumonia is in the majority of cases unilateral. The whole lung may be involved or only a portion. In the latter case the base is much more commonly affected than the apex. When due to the inhalation of irritating solid particles, both lungs are usually implicated.

Symptoms.—In the earlier stages of chronic pneumonia the symptoms are often very acute, and it is not uncommon to meet with advanced and extensive fibrosis in which the lung often must presumably have been of much longer duration than the symptoms accompanying it. In some cases the symptoms are directly continuous with those of some more acute pulmonary inflammation—an acute or a bronchopneumonia. Under these circumstances a prolongation of some of the phenomena of the original disease indicates the superincumbence of the pulmonary fibrosis. The pyrexia does not entirely disappear. There may be merely slight elevation of temperature towards evening or the course of the fever may be very irregular. The cough usually persists, as does also some increase in the frequency of the respiration and pulse, and the patient, instead of improving, gradually loses strength and flesh. At the same time the physical signs of the pulmonary consolidation remain, and gradually give place to those of pulmonary infarction. Where chronic pneumonia is secondary to pleurisy, a continuous sequence in the symptoms is less commonly observed. When the result of the inhalation of irritating solid particles, the symptoms of bronchial catarrh are predominant.

When the fibrosis is fully established the symptoms are usually more pronounced. They vary considerably, however, according to the extent of the lung involved, the quiescence or activity of the indurating process, and the presence or absence of bronchial catarrh. When bronchial catarrh is absent, and the disease is perfect quiescent, a considerable area, or even the whole of the lung, may be involved without producing any marked pulmonary symptoms, and slight dyspnoea, with some general impairment of nutrition and failure of strength, may be almost the only phenomena present. Such quiescence and immunity from symptoms, however, although common in the course of the disease, is rarely observed over very lengthened periods.

With the existence of catarrh of the bronchi, much more marked symptoms are observable. Inflammation of the bronchi is especially favoured by the dilatation of the tubes, and it is almost invariably present, to a greater or less extent, during the course of the disease; with it

is usually associated activity of the indurating process. The dilatation of the bronchi and secondary ulceration of their walls, which are so frequent, are also most important factors in accounting for the symptoms. The course of the disease now often simulates that of chronic phthisis, but it is for the most part more chronic, less regularly progressive, and more frequently interrupted by periods of quiescence. The dyspnoea is now more marked, and cough becomes a troublesome symptom. The cough may be more or less constant, and it is usually attended by expectoration. Its characters vary, however, according to the extent of bronchial dilatation and excoriation. When there are numerous dilated bronchi in the lower portions of the lung the secretion accumulates within them and its removal by expectoration becomes exceedingly difficult. Under these circumstances the cough is violent and pyrexia. The patient may remain for several hours with but little or no cough, and then occurs a violent paroxysm, which results in the expectoration of large quantities of muco-purulent secretion. This violent paroxysmal cough and copious expectoration, occurring at long intervals, are exceedingly characteristic of bronchial dilatation in the lower portion of a lung. According to Niemeyer, the pyrexia occurs when the secretion which accumulates in the lower portions of the lung reaches and irritates the more healthy bronchi which retain their contractility, the dilated tubes being so altered as to be completely insensible. The sputum may be simply puriform, but when there is much bronchial dilatation, owing to its accumulation and retention in the tubes, it usually undergoes putrefaction. It then often has a greyish or greenish-black colour, and is usually more or less fetid. This factor exists quite independently of gangrene, although it is more marked when gangrene is present. Haemoptysis is not unfrequent, but it is usually small in quantity. It is probably in most cases due to ulceration of the bronchial walls.

Pyrexia is usually present to a greater or less extent in the course of the disease. The fever, however, is exceedingly irregular, and there are often long periods of perfect immunity. During the pyrexial periods the maximum evening temperature is rarely more than 101° or 102° Fahr., and it may be only 100°. The morning temperature is often normal. The pyrexia appears in most cases to be due to inflammation and ulceration of the bronchi, and to the activity of the indurating process.

With the progress of the disease the patient gradually emaciates. The digestion becomes impaired, and diarrhoea is often present. Dropsy is a common symptom, although it is rarely extensive, and is, for the most part, confined to the lower extremities. It appears in most cases to be due to the anæmia and impeded pulmonary circulation. The pulmonary obstruction may also give rise to some enlargement of the right side of the heart, and cyanæmia. Lardaceous disease of the viscera is occasionally met with. Death usually results from the general failure of strength, or from some intercurrent affection of the opposite lung.

Physical signs.—In the earliest stage of

chronic pneumonia, when it is the result of a more acute pneumonic process, the physical signs are, in the main, those met with during the acute consolidation. It is the persistence of the signs of the pulmonary consolidation after the acute attack which indicates the possibility that the disease may become chronic. Dulness on percussion; increased vocal fremitus; bronchial breathing; and the existence of *râles*, which are larger, moister, and more metallic in quality than those of fine crepitation, are observable during this stage. When the induration is fully established, the physical signs are those of contraction and consolidation, with usually those of more or less dilatation of the bronchi, of a whole or a portion of the lung. The retraction is well-marked, and commonly affects the whole side, although when the lung is not universally involved it may be more limited. Expansion is exceedingly deficient, or completely absent. The heart is much displaced towards the affected side, the diaphragm and the abdominal viscera are drawn up, and the opposite lung encroaches considerably across the middle line in front. Percussion is hard, wooden, and high-pitched, sometimes more or less amphoric. The vocal fremitus is usually increased, and there is often bronchophony or pectoriloquy. The respiratory sounds will vary according to the extent of the bronchial dilatation and excavation, and the amount of secretion. They are for the most part bronchial, usually large and loud, and often distinctly cavernous. When there is much secretion in the dilated bronchi, high-pitched bubbling *râles* are heard, which are often amphoric and cavernous. These may be audible only after cough. The opposite lung is usually hyper-resonant, and the respiration exaggerated.

DIAGNOSIS.—The diagnosis of chronic pneumonia rests mainly on the physical signs. The diseases with which it is most liable to be confounded are chronic phthisis, and retraction from pleurisy. In the most chronic forms of phthisis, where the fibrosis of the lung is considerable, the diagnosis from non-phthisical consolidation may present some difficulty. This difficulty, however, rarely exists except in those cases in which the chronic pneumonia involves only the upper portions of the lung. Here the situation of the consolidation is very greatly in favour of its phthisical nature. This probability is infinitely increased if the other lung be affected. In unilateral basic disease, and in induration of the whole of one lung, the other lung being healthy, the question of phthisis can rarely present itself. Disease of the larynx is in favour of the phthisical, fœtidity of the sputa of the non-phthisical nature of the consolidation.

The retraction resulting from pleurisy with effusion may also be occasionally confounded with chronic pneumonia. Here, however, there are rarely the physical signs of dilatation of the bronchi, and the vocal fremitus is more commonly diminished. The presence of abundant fœtid sputa, of pyrexia, emaciation, &c., in chronic pneumonia will also in most cases render the diagnosis easy.

PROGNOSIS.—Chronic pneumonia, when it involves a considerable area of the lung, usually

tends ultimately to terminate in death, although under favourable circumstances life may be prolonged for many years. When the induration is more limited, and remains quiescent, the general health and duration of life may sometimes be but little affected. The most important element in the prognosis is the condition of the bronchi. The existence of bronchial inflammation, as evidenced by profuse expectoration, is always unfavourable, as it not only weakens the patient, but is usually attended by extension of the induration, and ultimately leads, in the dilated tubes, to ulceration of the bronchial walls and surrounding tissue, and occasionally to gangrene. Pyrexia, as another evidence of inflammation of the bronchi and indurated lung, is likewise unfavourable, as is also hæmoptysis. The latter indicates deep ulceration, and it may in exceptional cases endanger life. The general condition of the patient must also be taken into account in making a prognosis. Failure of strength and of digestive power, diarrhoea, and dropsy, are all of unfavourable augury.

TREATMENT. In considering the treatment of chronic pneumonia, it is in the first place important to bear in mind that the usual origin of the disease is some more acute pulmonary inflammation. Hence the necessity for the most careful management and supervision of such inflammations in their later stages, with the object of procuring a complete resolution of the pneumonic products.

When the fibrosis of the lung is established, it is hardly necessary to remark that the new growth is incapable of removal, and by treatment we can only hope to influence the extension of the disease, and control the bronchial catarrh with which it is so frequently associated. The frequency and gravity of bronchial catarrh has been already insisted upon, and its management, in the majority of cases, constitutes the most important element in the treatment. In that class of cases in which the disease owes its origin to the inhalation of irritating particles of solid matter, the removal of the patient from the source of irritation is obviously called for.

In the attempt to prevent and control bronchial catarrh, the question of climate must necessarily present itself, and very much may usually be done by residence at some suitable station. One not subject to vicissitudes of temperature, and at the same time dry and moderately bracing, is most likely to be beneficial. The patient should be warmly clad, and everything should be done, by means of diet and medicine, to improve the general health, inasmuch as the better the state of nutrition, the less is the liability to bronchial inflammation. Cod-liver oil and iron are often useful for this purpose. If an attack of acute bronchial catarrh supervenes it should be treated at once, and the importance of quickly controlling it should not be forgotten. In the medicinal treatment of the more chronic catarrhal process, which is so often associated with profuse secretion, much may usually be gained by the use of inhalations, of which turpentine, creosote, iodine, and carbolic acid are, perhaps, the most generally useful. These not only tend to diminish the amount of

secretion, but induce coughing and so assist in its evacuation. They also materially lessen fever. Turpentine may be administered internally with the same object. When the cough is excessive and prevents sleep, opium and chloral are most valuable. Counter-irritation, especiallyunctions with iodine, appear sometimes to be serviceable. Gastric disturbance, dyspnoea, hæmoptysis, &c., must be treated, as they arise, on general principles.

T. HENRY GREEN.

LUNGS, Inflation of.—This term is used somewhat ambiguously. It is sometimes employed as synonymous with emphysema in its general sense. More correctly it has been limited to that condition in which the lungs are acutely and temporarily distended more or less with air from various causes, such as plugging of the bronchial tubes, a condition which is usually called 'acute emphysema'. It cannot be said to give rise in itself to any definite symptoms, but it can be made out by physical examination, the signs being those indicating excess of air in the lungs.

When this condition exists, the aim in treatment should be to get rid of any obstruction leading to the imprisonment of the air, and to help the lungs in expelling it. It must be remembered that, even after a considerable degree of distension, the lungs may return to their normal dimensions.

Inflation is also a term applied to that expansion of the lungs with air, which is aimed at in the practice of artificial respiration.

FREDERICK T. ROBERTS.

LUNGS, Malformations of.—There are no malformations of the lungs which can be regarded as of much importance from a clinical point of view. As anatomical peculiarities the shape of these organs, or the arrangement of their lobes, may be abnormal. In a case which came under the notice of the writer, one of the lungs was improperly developed and unexpanded, in connection with the almost complete absence of one of the divisions of the pulmonary artery. The form of the lungs is frequently more or less altered, as the result of various organic diseases of these organs. FREDERICK T. ROBERTS.

LUNGS, Malignant Disease of.—SYNON: 1. *Carcinome du Poumon*, Ger. *Lungenkrebs*.
DEFINITION.—Malignant disease affecting the pulmonary tissues.

ÆTIOLOGY.—Malignant disease of the lungs is of more frequent occurrence than was at one time supposed. But there are not sufficient trustworthy statistics to enable us to determine its relative frequency to other forms of thoracic organic disease. It has been met with in persons of all ages, from childhood to extreme old age, but the middle periods of life, from 20 to 60, are the most liable, and the two sexes are about equally obnoxious to the disease. As a primary disease, originating in the lungs, cancer is undoubtedly rare, though much less rare as first manifesting its presence in those organs, either by local or general symptoms. In by far the larger number of cases the disease in the lungs is a secondary affection, consequent on the

transmission of cancer-cells, or blastema, from other parts, and in this way, with the exception of the liver, the lungs are more frequently implicated than any other internal organ. Thus, after the removal of an external cancer, pulmonary symptoms are among the most frequent and earliest indications that the disease has invaded internal organs.

ANATOMICAL CHARACTERS.—The right lung has been considered to be more frequently affected with malignant disease than the left. This, however, does not accord with the writer's experience. Of thirty-nine cases tabulated by him, the left lung was the principal seat in fourteen, and the right in nine only, whilst of the remainder either both lungs were affected, or the disease was confined to the mediastinum. Of the several varieties of cancer encephaloid is by far the most common in the lungs, colloid and epithelioma are the rarest, and scirrhus holds a middle place. The intramedullary varieties of these leading forms are also occasionally seen.

SYMPTOMS AND DIAGNOSIS.—In proceeding now to describe the various aspects under which these several varieties are presented to the clinical observer, their natural history and diagnosis, it is not proposed to maintain any precise distinction between primary and secondary forms, nor to discuss the minute anatomy or general pathology of the several species, such questions having been considered in other parts of this work. The object of the writer is to treat the subject from a clinical point of view. It is important, however, to observe, in passing, that cancer may either commence in, or eventually implicate any or all of the pulmonary textures; although undoubtedly both the primary localization and the spread of the disease are influenced by the particular species. Both the early symptoms and the subsequent progress of the case will often be materially modified by the particular tissue that is mainly implicated. If the disease first manifests itself in the form of sub-pleural growths, both the early symptoms and the subsequent phenomena will differ from those which present themselves when the disease commences in the deeper tissues of the lungs. And it is observable, that when the disease commences as disseminated deposits in the lungs, these deposits are frequently most numerous in the vicinity of the pleura, so that this membrane is very early implicated, in many cases, when it is not the primary seat of disease.

For clinical purposes we cannot do better than divide intra-thoracic cancerous growths into three groups. 1. Where the disease is *disseminated* through the lungs, either in the form of isolated scattered nodules of varying magnitude, or as spreading along the mucous membrane and sides of the bronchial tubes and vessels, through a greater or less extent of the lung. 2. Cases where the growth is more *localized*, occurring, for the most part, in large masses. 3. *Mediastinal tumours* involving the various structures at the root of the lungs, and eventually giving rise to symptoms of pressure and distress of a more or less serious character.

1. **Disseminated Malignant Disease.**—In the disseminated form of pulmonary cancer the symptoms vary considerably, according to the

ment of the growths. When the pleural surface is chiefly implicated, both the symptoms and the physical signs are essentially those of pleurisy, though the degree of febrile disturbance is usually very slight, and but little or perhaps no false membrane may be effused. The exudation is generally clear serum, or serum mixed with blood, and it may have a greenish or brown colour, but is rarely purulent or even semi-purulent. As the effusion increases in amount, the ordinary consequences of compression of the lung ensue, but dilatation of the side is generally much less marked than in simple pleurisy with effusion, in consequence of there being less giving way of the intercostals. The fluid generally returns speedily after paracentesis.

When the mucous and submucous membranes of the bronchi and the surrounding connective tissue are the chief seats of the disease, the physical signs are those of bronchial irritation and emphysema, which, however, may, for some time, be quite disproportionate to the dyspnoea and other symptoms of ordinary bronchitis. The expectoration is, for the most part, scanty, and either simply mucous or mixed with blood, or small bronchial casts may be expectorated. Examination with the microscope will occasionally reveal characteristic cancer-cells. The resonance of the chest may remain normal, when auscultation proves that there is a diminution of air entering the lung. But there will not be the hyper-resonance of emphysema. Wheezing and dry and moist sounds vary much with the amount of constriction of the tubes, and the amount and character of the secretion. But in advanced cases of this kind, by the spread of the disease along the interlobular septa and through the lung, its condition becomes similar to that of a cirrhotic lung, and the clinical aspects of the case may be greatly altered. Perhaps the most characteristic symptom of this class of cases is dyspnoea insidiously increasing, especially on exertion, without corresponding symptoms of either congestion of lung or compression. Of the general symptoms the most characteristic is that of steadily-advancing debility, which is common to other forms of cancer. And it is from asthenia, or from general cachexia, that the patient usually dies, before much or any disintegration of tissue takes place. It is the wirrhous variety of cancer which most often thus follows and implicates the bronchi.

In the distributive form, characterized by numerous masses, varying from the size of a millet-seed to that of a pea, scattered throughout the lungs, the clinical phenomena, both local and general, may very closely simulate those of tubercle, with recurrent attacks of bronchial irritation and congestion, and febrile disturbance. But as a rule, to which, however, some remarkable exceptions have been met with, there is little if any increase of temperature, nor is there the quickened breath and frequent dry cough of tubercle. The dyspnoea is chiefly on exertion, and seems more due to feeble circulation and general debility than to either pulmonary disease or febrile disturbance. Indeed the absence of local signs of inflammation, or symptoms of functional disturbance, are frequently

remarkable. Signs of bronchial irritation in some of these cases have been early noted and prominent symptoms; in others they have been slight and variable. The apices of the lungs, though often implicated, are not specially and early invaded as in tubercle, but rather the bases. If the cancerous growths are rapidly developed and extensively distributed through the lungs, both the signs and general symptoms become greatly modified, and the case proves speedily fatal. The similarity to acute tuberculosis is sometimes very close, especially in those instances in which there is marked febrile disturbance, and recurring slight hæmoptysis.

2 Localised Malignant Disease.—The second class of cases of malignant disease of the lungs, in which the disease manifests itself in the form of isolated masses of larger size, is the most common. There may be one such tumour or several at first assuming a rounded form, but as they gradually invade the lung, acquiring an indefinite shape, and involving a large portion or even the whole of the lung. Such tumours, being most frequently of the encapulated varieties of malignant disease, often grow rapidly, and as rapidly disintegrate, giving rise to hæmorrhage and destruction, not only of the mass itself, but also of the surrounding tissues. In this way vomica may be formed, or portions of lung may become gangrenous. The symptoms and progress of these cases necessarily vary much. If the growth or growths have attained any considerable size, there is dullness on percussion, and an absence of respiratory murmur over the affected portion of lung. The presence and character of other physical signs depend very much on the patency or occlusion of the bronchi. When as is often the case, these are completely occluded, nothing whatever may be detected on auscultation, and allied fremitus may be absent, the implicated portion being completely shut off from the rest of the lung and from all communication with the trachea. If, however, the bronchi remain patent, or—as the result of breaking down of the cancerous mass—if communication with the larger bronchi has been re-established, we have evidence of abundant secretion, and the ordinary phenomena associated with a cavity. In such circumstances microscopic examination of the expectorated matters may give decisive evidence of the nature of the case. On the other hand, before any such consequences have arisen, we may have in the case of a large tumour involving the whole or the greater part of one lung auscultatory signs which are with difficulty distinguishable from those of extensive pleuritic effusion. In other instances, where the portion of lung implicated in the cancerous growth is limited and well-defined, the physical signs may so closely resemble those of phthisis as to lead astray the most expert. Thus we may have limited dullness on percussion, with absence of respiration, followed by signs of surrounding irritation, slight hæmoptysis, cough, expectoration, and indications of a cavity. In some rare instances there have been limited flattening and altered form of the chest-walls, such as characterize chronic phthisis. Copious hæmoptysis, except in connection with extensive destruction of lung-tissue, is not common in cancer

of the lung. The diagnosis in these instances, where the local signs so closely resemble phthisis, must be based mainly on the constitutional symptoms, and the history of the case. There is considerable difference as to the progress and

- mode of termination in the whole of the class of cases now under consideration. Long before the local changes have advanced far enough to admit of a decisive diagnosis, the patient may die from rapidly-increasing debility and emaciation, with more or less of hectic fever, and even typhoid phenomena, or he may be carried off by rapidly-occurring pleuritic effusion. In other instances cancer developing in other organs is the cause of death. Indeed, in a large proportion of cases the manifestation of malignant growths in the neck, the axilla, or other parts, places beyond question the nature of the case. So long as the growth is confined to the substance of the lung, and does not implicate the nerve-trunks and larger vessels, there is usually little pain, proximal dyspnoea, or disturbance of the heart's action, excepting such as may be due to feebleness of muscular power. Nor is there generally any external oedema, or distension of the superficial veins. The reverse of all this characterises the cases in which the mediastinum and the roots of the lungs become involved.

3. **Mediastinal Tumours.**—This form of malignant disease of the lungs is described under a separate heading. See **MEDIASTINUM, Diseases of**.
PROGNOSIS AND TREATMENT.—The subject of the prognosis and treatment of malignant disease of the lungs in its various forms, will be more conveniently discussed in the article **MEDIASTINUM, Diseases of**.

J. RISON HENNETT.

LUNGS, Malpositions of.—Among malpositions may be regarded those conditions in which the lung is contracted more or less within its normal limits, or, on the other hand, distended so as to pass beyond its usual boundaries. One or both organs may be thus affected. These alterations may result either from more or less diminution of the amount of air in the lungs, as in cases of compression or collapse, from excess of the same, as in emphysema and hypertrophy, or from diseases which affect their structure. The lung may also be displaced by the pressure of tumours, in addition to being compressed. The most important malposition of the lung, however, is that known as *hernia*, in which a portion of the organ projects into the neck, or through some part of the chest-wall, or through the diaphragm into the abdominal cavity. If the hernia passes towards the surface of the body, it may be made out clinically, being indicated by a soft and compressible swelling, localized, resonant on percussion, and rendered more prominent by a cough. Pulmonary symptoms might possibly be present. It is impracticable to detect a hernia of the lungs through the diaphragm. **FREDERICK T. HOBKETT.**

LUNGS, Morbid Growths in.—The formations in the lungs which belong to the class of morbid growths may be thus enumerated, in the order of their importance:—1. *Tubercle*. 2. *Cancer*. 3. *Syphilitic granules*. 4. *Hydatids*. 5. *Rare formations*, such as sarcoma, enchondroma, osseous and myeloid growths, hemangioma, lymphatic formations &c. Most of these are discussed under their appropriate headings, and it is unnecessary to allude to them any further here. Those belonging to the last group are usually rather of pathological interest than of clinical importance, as they rarely give rise to any local symptoms or physical signs during life, and are merely discovered, as a rule, at the post-mortem examination. It is a question how far some of these growths are to be regarded as being of a malignant nature. In some cases they are secondary to similar growths elsewhere, or the lung may be involved by extension. Lymphatic formations in the lungs are sometimes observed in cases of Hodgkin's disease.

EFFECTS.—It may be useful to indicate the effects, if any, which morbid growths may produce in connection with the lungs. 1. The lung-tumours may merely be more or less displaced and compressed; or, in course of time, become absorbed or atrophied, in proportion as the growth progresses. 2. The distribution of air in the lungs may be modified by the mere presence of a growth, so that in one part it is in excess, and in another part deficient. 3. Similarly, the circulation of blood may be disturbed, leading to congestion in one part, and anæmia in another. 4. Morbid formations are very liable to cause local irritation. Hence they may induce bronchial congestion and catarrh, localized acute pneumonia and its consequences, or chronic interstitial pneumonia, which may lead to the formation of a fibrous capsule around a growth. 5. Certain formations are liable to undergo degenerative and destructive processes, either in themselves, or along with the pulmonary tissues. In this way they originate ulcerations or cavities, and may give rise to products, which are not only injurious to the lungs, but also infect distant parts to which they may be conveyed. After destruction reparative processes not unfrequently take place, with loss, however, of the involved portions of the lung-structures. It must be remarked here that some morbid growths seem to become infiltrated through the pulmonary tissues without destroying them; and under appropriate treatment the growth is absorbed, leaving the involved portion of the lung intact. This applies, for instance, to some cases of syphilitic infiltration. 6. Growths in the lungs sometimes extend beyond these organs, so as to interfere with neighbouring structures, causing irritation, pressure, or destructive effects. Thus, local pleurisy, pressure on vessels or nerves, destruction of bones, and other consequences may ensue. In short, the growths become then practically intra-thoracic tumours, and produce similar effects.

SYMPTOMS.—What has been stated as to the effects of morbid growths in the lungs will readily explain the clinical signs which they tend to originate. They may be of such little consequence that they produce no sign whatever during life, not interfering in any way with the respiratory functions, or being themselves insufficient amount to be discoverable by physical examination. Indeed, some formations may invade the lungs to a considerable extent so insidiously that no evident symptoms are induced.

3 M

The writer has known cases in which the lungs were extensively implicated in secondary cancer without any symptoms, except some feeling of shortness of breath on exertion. Usually, however, various degrees and combinations of the ordinary pulmonary symptoms may be anticipated—namely, pain in some part of the chest, cough, expectoration, the sputum sometimes containing fragments of the growth, hæmoptysis, and dyspnoea. Pressure-symptoms in connection with other structures are induced in some cases. Physical examination may detect the disease when there are no symptoms; or these may co-exist with physical signs, which either reveal the presence of the morbid formation itself—such as alteration in the shape and size of the chest, deficient expansion, dulness, bronchial or other abnormal breath-sounds, modified vocal fremitus and resonance; or of its effects on the lungs; or of the formation of cavities; or of its effects on neighbouring parts. The particulars relating to these points are discussed in other articles. Definite general symptoms are associated with many forms of morbid growth in the lungs.

TREATMENT.—The principles of treatment of morbid growths in the lungs are, first, to get rid of them, if possible, by medicinal means, as in the case of syphilis; secondly, to treat their effects; thirdly, to treat local symptoms which may arise; and fourthly, to treat the general symptoms. FERNEX T. KOWKA.

LUNGS, OEDEMA OF.—SYNON.: Fr. *Œdème du Poumon*; Ger. *Lungenödem*.

DEFINITION.—Infiltration of the pulmonary tissue with serous fluid.

The serous fluid is effused from the pulmonary capillaries into the pulmonary textures, and into the alveolar and bronchial spaces.

ÆTIOLOGY.—The causes of this exudation are manifold, but of two sorts—(a) *Disordered circulation*:—1. active congestion, attendant upon inflammatory conditions of the lungs and bronchi; 2. passive congestion; 3. mechanical congestion—in heart-diseases, emphysema, or pressure upon the pulmonary veins; 4. want of tone of vessels after inflammatory conditions, as pneumonia or bronchitis, or pressure upon the vagus nerve or pulmonary plexus; 5. afflux of blood to the lungs in cramp, and during the asthmatic paroxysms determined by the ineffectual efforts at inspiration. (b) *Morbid conditions of the blood*:—in albuminuria, and to a less degree in other diseases in which the condition of the blood is altered or impaired—for example, scurvy, purpura, anaemia, hydræmia—the lungs partaking of the general disposition to dropy.

ANATOMICAL CHARACTER.—In cases of œdema pulmonum, the lungs are usually large, filling the thoracic cavity, and sometimes indented by the ribs. They are heavy; their pleural surfaces are wet; and the pleural cavities contain an excess of serum. Both lungs are as a rule affected, their lower and most dependent portions chiefly; and one lung, on the side to which the patient has lain inclined, is more highly œdematous than the other. The higher the degree of œdema, the less crepitant the lung, and the more distinctly the surface pits on pres-

sure. A portion cut from a simply œdematous lung will, however, almost always float in water; but at the base of the lung there is usually some collapse in addition to the œdema, and a portion removed therefrom sinks. On section the lung exudes abundant thin serum, and more or less frothy fluid, with which the bronchial tubes are also occupied. On first making a section, the succulent tissue will break down easily under the finger, but, after the excess of fluid has been squeezed out, the lung feels toughened. (œdema may be found at any portion of the lung—at the apex, for instance, determined there by the inflammatory process. The transition between œdema and inflammatory consolidation is very gradual. œdema is also very apt to pass into, or to be complicated with, a certain degree of inflammation. The degree of friability, and of compressibility, and the application of the water test, are the readiest methods of distinguishing between the two. If a portion of œdematous lung be examined under the microscope, the alveoli are found to contain more or less numerous large granular cells, but these are never so numerous as to occupy entirely the alveoli.

SYMPTOMS.—The symptoms of œdema of the lungs are—in addition to those of the disease which has produced it—dyspnoea, which may amount to orthopnoea, troublesome retching, cough; and difficult, yet tolerably abundant, frothy, serous expectoration. The percussion note is deadened at both bases, although the dulness is usually more extensive at one base than the other; the vocal fremitus is diminished, the respiratory murmur is enfeebled or lost, and a fine bubbling crepitation is heard.

DIAGNOSIS.—The diagnosis of pulmonary œdema is not usually difficult. The absence of pleuritic pains and of fever, and the double-sidedness of the disease, together with the absence of any true bronchial breathing or ægophony, will exclude pneumonia or pleurisy. The presence of dulness will also distinguish the condition from simple capillary bronchitis, with a certain degree of which, however, it is often combined. The general condition of the patient, and the presence or absence of those diseases or circumstances which are known to produce œdema of the lungs, must be carefully taken into consideration. If, for instance, after an asthmatic paroxysm we hear some fine bubbling rales over the bases of the lungs, and find the patient expectorating an unusual quantity of frothy serous fluid, we may suspect pulmonary œdema rather than bronchitis.

PROGNOSIS.—The prognosis in œdema of the lungs depends mainly upon the general or local conditions with which it is associated. It is of very grave import in chronic Bright's disease or in heart-disease. It is also a grave complication in chronic bronchitis, showing failure of heart-power. It is, however, often a transient and unimportant affection when it succeeds to acute chest-affections, as pneumonia or bronchitis, or to asthma. As a complication of acute chest-affections, it is rarely recognised clinically.

TREATMENT.—The treatment of pulmonary œdema is, in all important cases, derivative. Stultices are to be applied to the chest, with

saft and mustard to produce redness. Dry-cupping will often give great relief. Blisters should be avoided. Watery purgatives should be administered, according to the strength of the patient. Diuretics are useful in some cases, especially the vegetable diuretics, such as digitalis, juniper, and scopolium, as also nitric ether; and the same is to be said of diaphoretics, for example, acetate of ammonia, warmth, air baths. Moderate stimulation and support must be kept up. Kidney or heart-disease if present will mainly determine the exact treatment. If there be failure of cardiac power, ether, ammonia, and alcoholic stimulants are required; and if the heart's action continues hurried or irregular, digitalis is especially indicated. When we suspect a loss of tone of vessels, as after bronchitis or pneumonia and in anæmic states, perchloride of iron with some mineral acid is to be recommended.

In all cases rest in bed or on a couch is necessary.

R. DOUGLAS POWELL.

LUNG, Perforation of.—**SYNON.**: The term *pneumothorax* is almost equivalent.

DEFINITION.—The formation of an opening through the pulmonary pleura, communicating with the interior of the lung.

ÆTIOLOGY.—Perforation of the lung may arise in many ways. Its causes may be classified under the three following headings:—

1. *Penetrating wounds*, for example, gunshot wound, punctured wound, or laceration by a broken rib.
2. *Diseases affecting the pleural cavity or neighbouring organs*; such as empyema, hepatic abscess or hydatid, or suppuration of the bronchial glands.
3. *Diseases affecting the lung itself*, for instance, phthisis, emphysema, gangrene, hydatids, or cancer.

Of all the causes of perforation of the lung, phthisis is infinitely the most common. It is the rule in phthisis for pleuritic adhesions to form *pari passu* with the pulmonary lesion, and these adhesions are usually very firm and difficult to break down. In neither respect, however, does this rule always hold good. In some rare cases in the earliest stage of the disease a small tubercular nodule situated immediately under the pleura softens, and the pleura gives way. Again, at any stage of the disease an outlying tubercular mass, situated below the point to which the pleural adhesions have extended, may soften and rupture into the pleural cavity.

In the more acute pneumonic varieties of phthisis there is often a singular indisposition to the formation of pleural adhesions. The pulmonary pleura in such cases becomes covered with a thin, smooth, translucent layer of lymph, shining through which can be seen at several points opaque yellow spots. These spots are found to correspond with underlying masses of softened cheesy material, by which the pleura has been undermined and deprived of its vascular supply. Pneumothorax has its most frequent origin in rupture of the pleura at one of these yellow points.

Finally, sinuses are sometimes found leading from old cavities within the lung to the pleural

surface. Occasionally these sinuses, the pleura being adherent, penetrate through the thoracic wall and point externally. In other cases, of which the writer has seen two examples, they may open into the opposite pleural cavity.

ANATOMICAL CHARACTERS.—The affected lung is in all cases collapsed, and in cases of old standing may be so completely so, and covered by such thick layers of lymph, as to be found only with difficulty. The opening may have closed. It is sometimes difficult to discern. It may consist of a small slit, communicating with a cavity by a slanting sinus, so as to form a complete valve, or it may be of considerable size, and communicate widely with a cavity or bronchus. All degrees of patency between these two extremes occur. The position of the opening is very variable, it is most commonly situated somewhere on the lateral or convex side of the lung. The rupture is almost always into the pleural cavity on the same side. It may, however, take place into the opposite pleural cavity, through the mediastinal fold of pleura. The pleura is inflamed, and covered with lymph; and its cavity contains air, and a greater or less quantity of purulent fluid. The heart is displaced, unless in some rare case it be held by a strong adhesion. Some years ago the writer tested the degree of air-pressure present in ten cases of pneumothorax by means of a water-pressure gauge. In two cases it was nil, in one case it was equal to 1.25 inch; in two cases 2 inches, in one case 3.75 inches, in two cases 4 inches; in one case 5.3 inches, and in a double case it equalled 3.5 inches in one pleura, and 2.7 in the other. The gas effused approximates in composition to that of expired air, containing from 8 to 16 per cent. of carbonic acid. Sometimes sulphuretted hydrogen also is found in fetid cases.

SYMPTOMS AND SIGNS.—The symptoms and signs of perforation of the pleura are those of pneumothorax and of hydro-pneumothorax. At the moment of attack sudden acute pain is felt in the chest, at the seat of rupture, and is immediately followed by great dyspnoea and shock. In a well-marked case the expression of face is peculiarly agonized and terror-stricken; the extremities are cold, damp sweats break out; the pulse is quick and small, and the respirations are exceedingly rapid. The position of the patient is that of orthopnoea, with an inclination forwards, and to the sound side; it is, however, frequently changed in the endeavour to gain breath. The voice is feeble and whispering. The urgency of the shock and dyspnoea depends upon the amount of useful lung suddenly disabled. If the patient survive the attack, after two or three days fever of a hectic character, with sweats, supervenes. In some cases, however, the symptoms of pneumothorax come on very insidiously.

Physical signs.—The physical signs are very characteristic. There is enlargement of the side affected, and effacement or bulging of the intercostal spaces. The heart is displaced towards the sound side. The percussion-note is hyper-resonant or tympanic over the side affected, except where (at the apex) the lung may perhaps be still adherent; and on auscultation either no respiration at all is audible, or amphoric breathing of a peculiar character may be heard.

at one or more points, sometimes accompanied with the characteristic metallic tinkle. A peculiar metallic echo is heard if the patient coughs. If, whilst the ear is applied, a coin placed on the diseased side is struck with another coin, a characteristic bell-note is heard. The vocal fremitus is diminished or lost. At a later stage, when more or less effusion has taken place, the signs of hydro-pneumothorax present themselves, namely, dulness below and hyper-resonance above—in varying proportions and shifting in relative position with the posture of the patient. If the amount of fluid be moderate, a splash or succussion-sound may be elicited. This sound may be audible to the ear applied to the chest, or to bystanders. If the fluid effusion be considerable, intercostal fluctuation may be felt; and this fluctuation gives to the finger, on percussion at the level of junction of air and fluid, a peculiar sensation of thrill. The position usually assumed by the patient now is with the head raised, and leaning towards the diseased side.

DIAGNOSIS.—The diagnosis of perforation of the lung is to be made from other diseases, and also with respect to the probable nature of the opening, and the degree of pressure present. If the three essential signs of pneumothorax be remembered, namely, displacement of heart, tympanitic percussion-note, and either absence of respiration or amphoric breathing, there can scarcely be any difficulty in making the diagnosis. It cannot be confounded with a bilateral disease like emphysema. The shifting resonance and dulness, the succussion-splash, with perhaps metallic tinkle and amphoric breath-sound, are signs abundantly sufficient to distinguish hydro-pneumothorax from ordinary emphysema. Respecting the nature of the opening—whether valvular or free, careful auscultation will usually gain the desired information. If amphoric breathing be well-marked, it may be assumed that the opening is a free and tolerably direct one; if, on the other hand, no respiratory sound be audible, the communication with the pleura is indirect and more or less completely valvular. In the latter case the pressure-symptoms become more urgent.

PROGNOSIS.—Of course the prognosis in every case of tubercular pneumothorax is necessarily very grave, but by no means equally grave in all cases. The following considerations will guide to a correct prognosis. (a) *Nature of opening.* If the communication with the pleura be valvular, signified by the entire absence of breath-sound, and the increasing urgency of dyspnoea, the patient will die in a few hours, unless relieved by paracentesis. (b) *State of the opposite lung.* If the effusion of air have occurred on the side least affected by previous disease, the case is correspondingly hopeless. If, on the other hand, we know that the lung now collapsed was previously much diseased, and if the other lung be but little affected, the duration of life may not be greatly shortened by the accident. Life is then gradually extinguished by hectic fever, and progressive disease in the opposite lung. It is by no means impossible, and probably happens more frequently than is supposed, that the opening in the pleura may close, the air become absorbed, and the case converted into one of

simple emphysema. In pneumothorax arising from accidental wound or injury to the lung, the prognosis depends upon the visceral injury. The air in the pleura is absorbed with considerable readiness.

TREATMENT.—In all cases in which death is threatened by asphyxia, in consequence of air accumulating in the pleura, paracentesis with a fine trochar must be performed. This will in such cases give great relief, and may be repeated if necessary. There is a tendency for an opening at first completely valvular to become at a later period more patent or possibly to close so that it is better to operate when necessary with a fine trochar than to make a permanent opening. Rest to the affected side should be secured, as far as possible, by the application of a broad piece of strapping extending round the side to beyond the middle line in front and behind. The shock and dyspnoea are best treated by opium in repeated small doses. Stimulants may also be necessary, but opium is far more useful.

R. DOUGLAS POWELL.

LUNG, Rupture of.—Rupture of the lung is an extremely rare occurrence. Cases of so-called rupture of the lung from external violence are, for the most part, really produced by perforation or laceration of the pleura by a fractured rib. It is said that rupture of the lung may occur in whooping-cough.

LUNGS, Syphilitic Disease of.—There is still much uncertainty as to the effects which syphilis may produce in connection with the lungs, but there can be no doubt that it does sometimes originate specific lesions in these organs, though much less frequently than in most of the other viscera. They are generally only met with in advanced cases of acquired syphilis, when the signs of the disease are markedly developed in other parts. Occasionally the lungs are involved in congenital syphilis. The presence of a tubercular or scrofulous diathesis has been supposed to predispose to the implication of the lungs in syphilitic disease.

ANATOMICAL CHARACTERS.—Gummata constitute the most certain and unquestionable lesions of a syphilitic nature in the lungs, but they are rare. When present, they vary in number from one to many. In the latter case they are disseminated, but are stated to have a predilection for the deeper parts of the organs. In size these growths usually vary from a pea to a walnut, but may reach the dimensions of a large egg. They are generally well-defined, rounded in shape, and often surrounded with a fibrous capsule. In their early condition gummata in the lungs appear on section greenish or brownish-red, homogeneous, firm, and dryish in consistence. Subsequently they tend to degenerate, becoming more or less caseous, yellow, and less consistent; and they may even break down in the centre, so as to form cavities. The structure of these gummata is found on microscopic examination to be made up of imperfect fibres, abortive nuclei, and a few fibro-cells, infiltrating the pulmonary tissue, and thickening the alveoli. Afterwards these are mixed with granular matter and other products of degeneration and disintegration.

There has been much discussion regarding the

relation of syphilis to another form of lesion affecting the lung-tissues, namely, a variety of chronic interstitial pneumonia. There seems every reason to believe that this morbid condition is in some instances due to syphilis. The result is a fibroid infiltration of the pulmonary tissue, which in its general and microscopic characters cannot be distinguished from a similar condition due to interstitial pneumonia from other causes, but the new tissue is said to be more vascular in its early stages. The affected parts are much indurated, and any bronchi which are implicated tend to become more or less dilated. The morbid condition may be distributed in various parts of the lungs, but appears to have a preference for their bases and the vicinity of their roots. It frequently originates at the surface, and penetrates thence into the interior of the lungs in the form of fibrous bands, the pleura being generally thickened or adherent, and superficial puckering and depressions being visible. In other instances the new growth commences around gummata; or from a chronic contracting peri-bronchitis, associated with ulcerative inflammation (Pye-Smith). Dr. Green states that it originates mainly around the small interlobular blood-vessels. Syphilitic fibroid infiltration has no tendency to cessation; but it may become the seat of ulceration or gangrene.

In connection with congenital syphilis, a peculiar condition has been described as affecting the lungs in new-born or very young infants, under various names, such as syphilitic pneumonia, white hepatization, and epithelioma of the lungs. It assumes a more or less diffuse or infiltrated arrangement, but is of variable extent, and may involve one or both organs. One lung may be affected throughout, while the other is quite free from disease. The more obvious characters are as follows:—The pleura is usually unaffected. The lung is enlarged, and may be in a state of full expansion, so that its surface is marked by the ribs, it feels remarkably heavy; and at the seat of the disease is dense, firm, hard, and usually resistant, not breaking down under pressure. On section it presents a white or yellowish-white colour, being more or less bloodless; is uniform and smooth, and little or no fluid can be expressed or scraped from the cut surface. Careful examination reveals minute bands of fibrous tissue running in all directions. Microscopically the change seems to consist mainly in thickening of the alveolar walls and minute bronchi, due to an imperfectly fibrillated and unelastic tissue, which undergoes degenerative changes. Most observers further describe an increase in the epithelial cells, which fill the air-vessels and minute air-tubes, but Wagner denies this. The vessels also become thickened and ultimately obliterated.

It may be remarked that the bronchial tubes or their divisions may be affected with syphilitic disease, their submucous tissue, or occasionally their deeper structures, becoming infiltrated with a fibro-nuclear growth. Ulceration may take place, followed by cicatrization, and leading to thickening of their walls, and narrowing or even complete closure of their channel.

SYMPTOMS.—In the present state of knowledge it is impossible to write with anything like defini-

ness respecting the clinical history of syphilitic disease of the lungs. As a matter of fact, in the majority of cases the lesions have only been discovered after death, no symptoms having occurred during life pointing to the lungs; or, these having been obscured by symptoms affecting other parts. In a case of recognized constitutional syphilis, attention should be paid to the lungs as well as to other organs, and it would be advisable to examine them from time to time, as physical signs might occur without any obvious symptoms to attract the patient's attention. If pulmonary symptoms should arise in a person undoubtedly syphilitic, or who had had syphilis, the possibility of the lungs being affected should specially be borne in mind. Among these symptoms hæmoptysis at an early period is said to be important. Physical examination might possibly reveal the presence of gummata, as evidenced by localised dulness, bronchial breathing, increased vocal fremitus and resonance, and other signs of consolidation. The most significant signs, however, are those indicating marked induration of the lung from fibroid infiltration, especially if unilateral, and confined to the base or middle portion of the organ. In course of time signs of cavities might become evident, due to breaking-down of gummata, or to dilated bronchi. The general symptoms are those of constitutional syphilis, combined with those of phthisis. There is but little or no pyrexia accompanying the pulmonary lesions; and the progress of the case is essentially chronic. The effects of treatment may be of peculiar significance in the diagnosis of syphilitic disease of the lungs. If such symptoms and physical signs connected with these organs as have been indicated above should disappear under the use of anti-syphilitic remedies, a diagnosis of this disease might fairly be made. Indeed some observers think that they frequently discover and cure it, out this is somewhat doubtful.

TREATMENT.—If syphilitic disease of the lungs be recognised or suspected, the appropriate treatment in most cases is to administer iodide of potassium freely and continuously. In some cases a mercurial course of treatment answers best; or perchloride of mercury might be combined with the iodide. It may be necessary to employ internal remedies or local applications for the relief of pulmonary symptoms. Cod-liver oil and tonics may be given with advantage for the amelioration of the general condition, in cases where such medicines are needed.

FREDERICK T. ROBERTS.

LUNGS, Tuberculosis of.—Tubercle is the most important morbid growth affecting the lung, but it is by no means a settled point what should be included under this term. Many pathologists only recognise as tubercle the so-called grey granulations; others regard the various masses and infiltrations noticed in cases of phthisis as of this nature, and they look upon tubercle in these organs as divisible into grey and yellow varieties, and arranged either in granules or as an infiltration. It is unnecessary in this place to discuss this subject further, as it is considered fully in other appropriate articles. See PHTHISIS, and TUBERCULOSIS. FREDERICK T. ROBERTS.

LUPUS ERYTHEMATOSUS (*lupus*, a wolf, or a rodent disease; and *erythematous*, related to erythema).—**SYNON.**: *Seborrhoea congestiva*.

DEFINITION.—A chronic hyperæmia of the skin, attended by a new cell-growth, followed by interstitial absorption, and ending in scar.

ÆTIOLOGY.—Women are more liable to lupus erythematosus than men, in the proportion of 8 or 10 to 1. It is rare before puberty, and most often begins between the ages of 20 and 30 years, but no age of adult life up to 60 or 70 is exempt. Weakly persons are thought by some to be most liable, but it may attack perfectly healthy people—at any rate there is no intimate connection with any other special disease. This affection is not hereditary. It attacks all classes of society.

ANATOMICAL CHARACTERS.—The capillaries of the cutis are dilated, and a small-celled new-growth develops in it, close under the epidermis, around the orifices of the sebaceous and hair-follicles and the sweat-ducts. There is an increased secretion of sebum; and crusts of epidermis and fatty matter form. The terminal scar is due to destruction of normal tissue by the new-growth; partial fatty degeneration and absorption of the latter; and conversion of the remainder into permanent connective-tissue.

SYMPTOMS.—Lupus erythematosus most often attacks the face. Small patches of well-defined crimson or purplish redness form on the skin of the cheeks or nose, and remain for a long period unaltered; they then become covered in parts with thin, firmly adherent, dirty-looking crusts, which if removed are found to send processes into the dilated mouths of the sebaceous glands. In the final stage, the redness gives place to a very superficial whitish scar. Confluence of several small patches gives rise to irregular patterns. When both cheeks are attacked at once, the patches tend to unite across the nose in the shape of a bat's wing or butterfly. The scalp often suffers, and there is permanent loss of hair. Other seats of lupus erythematosus are the ears, eyelids, lips, and backs of the hands, but it may exceptionally occur on the arms and legs, on the trunk, and on several parts at one time. There is no pain, or ulceration, but sometimes slight itching. Exposure to cold winds or to great heat aggravates the disease. In Germany an acute form has been observed, in which the eruption quickly covers a large part of the body; is attended with fever and prostration, and may end in death. The writer has seen such a case.

COMPLICATIONS.—Recurrent erysipelas has been noticed more often in lupus erythematosus than in lupus vulgaris. These two forms of lupus may occur in the same individual.

DIAGNOSIS.—This disease is to be diagnosed from lupus vulgaris, by its commencement after puberty; by its very superficial character; and by the sebaceous crusts. From eczema, which it sometimes resembles at first sight, lupus erythematosus may be distinguished by the history, chronicity, trifling itching, and the presence of scars. For its diagnosis from acne rosacea see Acne.

PROGNOSIS.—This disease is very chronic, and may last for years. Permanent cure is very difficult, on account of the tendency to relapse.

Except in the acute form, which is rare, there is no danger to life.

TREATMENT.—In the treatment, of lupus erythematosus the first indication is to rectify any derangement of the general health. There is no specific internal remedy. Arsenic and mercury are not indicated; milk and cod-liver oil improve the nutrition. Externally, mild caustics suit best. Emplastrum hydrargyri should always be tried, spread thickly on linen, with enough oleum terebinthine to make it soft, and applied every night for a long period. The liniment or tincture of iodine can be painted on until slight inflammation is set up, and repeated after an interval, or spirit of soap (*R. saponis mollis ℥j, spiritus vini 5ss-℥j*) may be rubbed in in the same way, and let dry on. Stronger caustics, such as the solution of caustic potash, require great caution in their use (see LUPUS VULGARIS). Some cases do best with soothing remedies—such as unguentum zinci benzoati, or a lead lotion (*R. liquoris plumbi subacetatis ℥j, glycerini, ʒij*) applied warm after the crusts are removed; and the latter are always of service in the intervals between the caustics.

EDWARD I. SPAEKS.

LUPUS VULGARIS (*lupus*, a wolf, or a rodent disease; and *vulgaris*, common).—**SYNON.**: *Fr. Scrofulide maligne; Dartre rongeanle; Ger. Lupus; Französ. Flechte*.

DEFINITION.—A very chronic non-contagious disease of the skin and mucous membranes; chiefly due to an infiltration of small round cells into their substance; attended either with epidermic exfoliation, interstitial absorption, or destructive ulceration.

ÆTIOLOGY.—The ætiology of lupus vulgaris is unknown. Some cases occur in scrofulous persons with enlarged or suppurating lymphatic glands, diseases of the bones and joints, &c., or in the children of consumptive parents, but in the larger number lupus affects perfectly healthy people. Most cases begin very early in life, from the second or third year up to puberty. The ulcerative form—*lupus exedens*—may begin still later, but it is very rare for it to do so after the thirtieth year. Women are somewhat more liable to lupus than men, and country people than townspeople. It is in no way due to syphilis, either hereditary or acquired; and instances in which two members of the same family are attacked are rare.

ANATOMICAL CHARACTERS.—The cutis in lupus is infiltrated with vast numbers of small round cells of about 0.004 mm. in diameter, which encroach on and gradually destroy its proper tissues. The new-growth has a certain resemblance to granulation-tissue (Virchow). It is highly vascular, and contains new-formed capillary vessels. Nodules have been described, disseminated through the cutis, each consisting of one or more central multinuclear giant-cells, surrounded by bands of smaller cells which shade off into the granulation-tissue. These nodules exactly resemble grey tubercle (Friedländer). Some authorities regard these giant-cells as retrograde products, due to central fusion of the endothelial cells of sweat-ducts, blood-vessels, and lymphatics, with persistence of their nuclei (Lang). The epidermis covering the lupus-tissue is thick-

ened; the lower cells of the rete mucosum are at last degenerated, and contain reddish pigment. Lupus-tissue is very persistent. It may either undergo fatty degeneration and subsequent absorption, without lesion of the epidermis; or else the latter breaks down too, and ulceration is the result.

SYMPTOMS.—Lupus usually begins as one or more small, smooth, reddish-brown, or reddish-yellow blotches, from the size of a pin's head to a split pea, which may be level with the skin, or else raised in the form of small tubercles. Several of these are generally aggregated into a patch, and a number of them may coalesce, so as to cover extensive surfaces of skin; but this is the exception rather than the rule. Any change that occurs is always slow, and a patch the size of a shilling or a florin may take years to form. In the non-ulcerative variety, thin, epidermic scales are continually thrown off from the surface of the tubercles—*Lupus exfoliatus*. After a while, interstitial absorption of the lupus-cells begins in the older tubercles, and a bluish-white papery scar is left. In other cases the tubercles soften, ulcerate, and become covered with greenish-yellow adherent scales, beneath which the ulcer extends. The surrounding parts are swollen, and the edge of the ulcer is pinkish. Removal of the scab exposes a loss of substance, with sharp-cut edges, and a granulating base covered with purulent secretion. The ulceration may attack structures deeper than the skin, and destroy cartilage, fibrous tissues, muscle, and even bone. The mucous membranes are not often primarily affected by lupus, though it often extends to them from the skin; instances are, however, recorded in which the larynx has been attacked, causing ulceration, partial destruction of the epiglottis, and warty outgrowths on the posterior wall.

Lupus may occur on any part of the body or limbs, but it has a special preference for the skin of the face. The non-ulcerative form chiefly selects the cheeks, and afterwards, in order of frequency, the nose, ears, legs, arms, and trunk. The ulcerative form—*Lupus exedens*—begins almost exclusively on the nose, attacking chiefly its anterior portion, either the tip or the edges of the alae. Sometimes it begins within the nostril. Unless proper treatment is at hand the nose may be entirely destroyed, and severe scars made into the tissues of the cheeks, lips, and other neighbouring parts.

COMPLICATIONS AND SEQUELAE.—Lupus may co-exist with enlarged and suppurating glands in the neck and elsewhere; with various scrofulous affections; with phthisis, and with chronic Bright's disease. Great deformity may result from the contraction of the scars which it leaves, for example, ectropion, stricture of the nares, and distortion of the mouth. About a dozen cases have been recorded in which epithelioma developed on a patch of lupus of many years' standing, or on a lupus scar. We may regard such cases as arising from the stimulus of the proliferative processes in the cutis on the neighbouring epithelium.

DIAGNOSIS.—The duration and position of lupus vulgaris, and the absence of thick scalliness and

itching, will generally render it easy to distinguish this disease from circumscribed forms of psoriasis and eczema; and its commencement in early life will clearly separate it from epithelial cancer and rodent ulcer. It is with syphilis that it is most apt to be confounded, and the diagnosis between lupus exedens on the nose, and an ulcerating syphilitic, is sometimes extremely difficult, or at first sight impossible. In these cases, after carefully considering the history, we must examine other parts of the body for traces of syphilis, and an inspection of the mouth and pharynx will often materially assist us; and lastly, the greater chronicity and slower extension of lupus, as well as its resistance to specific treatment, will generally lead to a correct opinion. Incidence is a character of special value in deciding between lupus and syphilis, particularly as affecting the mucous membranes. Syphilis has also more tendency to supuration than lupus.

PROGNOSIS.—Lupus is never fatal *per se*, but it can never be looked on in a favourable light, owing to its tendency to relapse under treatment, and its invariable termination in a contracting cicatrix.

TREATMENT.—*Internal.*—Internal treatment is only of use in lupus vulgaris where the patient's general health is bad, or where well-marked symptoms of scrofula are present. In these cases great benefit may be derived from tonics, especially the saline of iron, and from cod-liver oil in as large doses as can be tolerated. Nutritious food should be freely given, and the patient should take plenty of outdoor exercise in a bracing climate.

External.—The real cure for all forms of lupus must always consist in the destruction of the new tissue forming it, by caustic agents of various strengths. A number of such remedies have been proposed, but the successful application of each seems often to depend more on individual experience of its use, than on the superiority of any one caustic over the rest. The caustics most generally used are caustic potash, nitrate of silver, and acid nitrate of mercury. Equal parts of caustic potash and distilled water may be applied with a tiny piece of sponge, so as to limit the action as much as possible. The pain which follows is not of long duration—a point of much importance where a caustic must be repeatedly used. Solid nitrate of silver should be bored freely into all ulcerated parts or soft tubercles. The lupus-tissue offers but slight resistance to it, whereas it will not penetrate or injure healthy parts. Acid nitrate of mercury may be painted on with a glass brush. The crusts which form after any of these agents, fall off in ten days or a fortnight, and it is not advisable to repeat the application at shorter intervals. As a rule no dressing except zinc ointment is required. Some authorities prefer the actual or else the galvanic cautery, but both these measures have the disadvantage of disfiguring the parts, so that it is difficult to determine when healthy tissues are reached. Others advise multiple scarification, with one or more fine-bladed knives, so as to obliterate blood-vessels, and produce absorption by starving the lupus tissue and exciting inflammation.

(Volkman, Vesel). For a more detailed description of the mechanical methods of treatment, including that by 'scraping,' see *ARTHRITIS*. In the treatment of the superficial patches of lupus non-exedens, the repeated application of mercurial plaster during several months has sometimes been followed by absorption of the growth. Pyrogallie acid ointment (1 to 10) has been used by Hebra and others with much success. In other cases painting with tincture or liniment of iodine, and coating with gutta-percha foil, produces slow improvement; and where no ulceration exists, demanding active interference, these milder remedies deserve a trial. See *ARTHRITIS*.
EDWARD I. SPANER.

LYMPH (λύφην, aymph, water).—Physiologically, lymph signifies the fluid which circulates in the lymphatic system. Pathologically, the term is applied to the coagulable exudation which escapes from the vessels in inflammation. The name 'vaccine lymph,' or 'lymph,' is also given to the fluid contained in the vaccine-vesicle. See *INFLAMMATION*; and *VACCINIA*.

LYMPHADENITIS (*lymphā*, lymph, and *adenitis*, inflammation of a gland).—Inflammation of lymphatic glands. See *LYMPHATIC SYSTEM*, Diseases of.

LYMPHADENOMA.—Стромъ Hodgkin's Disease; *Anæmia Lymphatica* (Wilks), *Fr. Adénie* (Trousseau); *Lymphadénie* (Kauvier); *Ger. Pseudoleukämie* (Wunderlich).

DEFINITION.—A disease characterized by more or less widely-spread enlargement of the lymphatic glands, accompanied frequently by enlargement of the spleen, and by progressive anæmia.

HISTORY.—Cases of coincident enlargement of the lymphatic glands and spleen were noted by Malpighi (1669) and Morgagni (1762). The nature of the glandular change was first carefully described by Orsiggie, (1843); and the general clinical history of the affection was pointed out by Hodgkin (1832), and by Wilks (1856). The most important subsequent observations are those of Virchow (1864), Wilks (1865), Trousseau (1866), Wunderlich (1866 and 1866), and Murchison (1870).

NATURE.—The enlargement of the lymphatic glands, which consists at first of mere hyperplasia, and subsequently of fibroid induration, varies much in its extent. A few glands only may suffer, or every gland in the body may be enlarged. The former cases have the characters of a local growth; the latter is distinctly a general disease, for which the term *lymphadenitis* seems the most exact. The glands vary in consistence: when soft there may be a considerable excess of leucocytes in the blood; when hard there may be simple anæmia. This difference does not afford sufficient ground for separation. The enlargement of the spleen is usually due to disseminated growths, arising in the Malpighian bodies: sometimes there is also hyperplasia of the splenic pulp, as in splenic leucocythæmia.

ETIOLOGY.—In two-thirds of the cases of lymphadenoma, no cause can be traced, and the numerous antecedents of the disease, in most of the remaining cases, evidently constitute only a small part of the influence to which it is due. Hereditary transmission has not been distinctly

proved. The disease is three times as frequent in males as in females. It is met with at all ages, but is most frequent in early and late adult life. It occurs, but is not specially frequent, in children under ten years, and, having regard to the numbers living, it is least frequent between the ages of forty and fifty years. Intemperance, mental depression, insufficient food, and over-exertion have been noted, in rare cases, as antecedents. Exposure to cold, in several instances, has appeared to be the exciting cause of the affection. It is doubtful whether the disease has any relation to constitutional syphilis. In several cases the symptoms have first appeared after child-birth. Various febrile affections have, in a few instances, preceded the affection. The exciting cause which has been noted most frequently is some local irritation, as of a decayed tooth, discharge from the ear, sore-throat, inflammation of the lachrymal sac, or eczema. In these cases the glands nearest the source of irritation first enlarged, and then more distant ones became affected.

ANATOMICAL CHARACTERS.—The several groups of glands are affected in the following order of frequency, beginning with those most commonly diseased: cervical, axillary, inguinal, retro-peritoneal, bronchial, mediastinal, mesenteric. Sub-idiary adjacent glands are often enlarged together with the chief groups, and nodular growths, similar to enlarged glands, arise in the course of the lymphatics in places in which the existence of glands is not usually recognized, so that continuous chains of nodules connect the various groups. The size attained by the glands in lymphadenoma varies from that of a bean to that of a hen's egg. At first the individual glands are separate and movable one on another. Ultimately they often unite to form a conglomerate mass, in consequence, in most cases, of the perforation of the capsules of the glands by growth, which may also invade adjacent parts. The cervical glands are usually enlarged in both the anterior and posterior triangle; and the sub-maxillary glands may encircle the neck beneath the lower jaw. They may press on the trachea or larynx, displace the latter, compress the internal jugular vein, and cause paralysis of the recurrent laryngeal nerve. The occipital glands are usually also enlarged. The axillary glands often form a mass of very large size, and prolongations may extend beneath the pectoral muscle. The glands in the anterior mediastinum frequently suffer, and the growth may extend to adjacent structures, such as the pericardium, which may be perforated. The thymus may be involved, secondarily or primarily, or may escape. The bronchial glands are diseased more frequently than the cardiac glands, and the trachea and bronchi may be pressed upon, or the lung invaded. The retro-peritoneal glands often form a mass of large size, which may surround and compress the solar plexus, causing symptoms similar to those of Addison's disease. Enlargement of the mesenteric glands is neither common nor considerable. The inguinal group is frequently diseased, and the femoral vessels and crural nerves may be thereby compressed. The consistence of the enlarged glands may be either soft or very hard. Usually

the longer the enlargement has existed, the firmer are the glands. Their section is more uniform than in health. The colour is yellowish or whitish-grey. In the firmer glands dense tracts of fibrous tissue are seen to pass in different directions. Rarely the follicles have a different appearance being opaque and yellowish from fatty degeneration, whilst the septa are white and conspicuous, from fibrous thickening. Causation is, however, rare, and when it occurs is commonly confined to one or two glands. When causation is general, the cases are of a form intermediate between lymphadenoma and scrofula. The softer glands yield a juice on rasping, the firmer glands yield no juice. In the former, the only histological change is an enormous increase in the cellular elements—the lymph-corpuscles of the reticulum, but the relations of the septa and follicles often remain normal. Sometimes the cell-growth invades the septa which become split up and disappear, and it may even, in a similar manner, perforate the capsule. The firmer glands present much fibrous tissue, which may be confined to the septa, or invade also the delicate network in the substance of the gland, and then the cells gradually disappear, and the whole substance of the gland may be transformed into a fibrous mass. The tracts of fibrous tissue may have under the microscope a peculiar vitreous aspect, especially around the arteries.

The spleen is diseased in at least four-fifths of the cases, usually in consequence of disseminated growths, often irregular in shape, arising from the Malpighian corpuscles, yellowish or greyish white, rarely caesating, and usually corresponding in consistence, and resembling in structure, the glands in the same case. The splenic pulp may be normal in quantity, or may be compressed and atrophied. In some cases it is also increased in quantity, and this increase may even be the sole change. In such cases the morbid changes of lymphadenoma and splenic leucocythæmia coexist, and there is often a much greater increase in the white corpuscles of the blood, than when the spleen is the seat of simple growths. The size attained, in the cases of nodular growths, is not great, the weight being from ten to thirty ounces. When the splenic pulp is increased, the size attained is rather greater. In the latter case the enlargement is uniform, while it may be irregular when there are growths. The medulla of bones has been found, in rare cases, to present a change similar to that met with in splenic leucocythæmia and pernicious anemia. Collections of adipoid tissue elsewhere often undergo changes similar to that of the lymphatic glands. The tonsils, the mucous membrane of the pharynx, the œsophagus, the stomach, and the large and small intestines, may all be the seat of growths, originating in the follicular glands, and sometimes ulcerating. The liver is often the seat of scattered lymphoid growths, usually minute varying in size from a small pea to a pin's-head. They occupy the interlobular spaces. Rarely larger nodular growths are found. In other cases the liver is simply congested. Similar minute growths are often found in the kidneys, chiefly in the cortex; and

these organs may also be the seat of parenchymatous degeneration. The peritoneum may be inflamed over enlarged glands, or may be the seat of growths. Growths have also been found in the testicles; and frequently in the lungs, where they may break down and form cavities.

SYMPTOMS.—The most important symptoms of lymphadenoma are due to the altered blood-state, and to the enlarged glands. The latter cause the earliest symptoms, and the cervical glands are commonly the first to enlarge. When the internal glands are primarily affected, pain and pressure-signs may precede other symptoms. Occasionally the signs of anemia precede those of the local change, and, in rare instances, irregular febrile disturbance may occur before the glandular enlargement. The affected glands are smooth, and present, at first, a peculiar mobility, which may disappear when they become adherent, and constitute an irregular lobular tumour of some size. They are usually painless, except during periods of rapid growth. A diminution in size has been observed before death. The enlargement of the cervical glands may cause the neck to equal, or even exceed, the head in circumference. The pressure on the veins may cause symptoms of passive cerebral congestion. The larynx may be displaced, and the movements of the lower jaw may be interfered with. Pressure on the trachea, by the glands in the neck and in the posterior mediastinum, may cause dyspnoea and even death by suffocation. That on the pharynx and œsophagus may obstruct deglutition, and cause death by starvation. The enlargement of the axillary and inguinal glands may interfere with the movement of the limbs, and impede the circulation. Various and serious pressure-effects result from the enlargement of the thoracic and abdominal glands, obstruction in veins, pressure on nerves, &c. The enlargement of the spleen can usually readily be felt, but does not commonly give rise to symptoms. Anæmia is one of the conspicuous symptoms, and may precede, or succeed, obtrusive affection of the glands. The red corpuscles may be reduced to fifty, thirty, and even twenty-five per cent. of the normal. In most cases there is no marked excess of white corpuscles, but occasionally they are much more numerous than normal. In almost all cases in which their excess is comparable to that met with in splenic leucocythæmia, the splenic pulp is increased in quantity, and the lesions of splenic leucocythæmia and of lymphadenoma are conjoined. The liver may be enlarged from the disseminated growths, and from congestion. Jaundice only occurs from the pressure of enlarged portal glands upon the bile-ducts. Ascites may be due to similar pressure, or to the blood-state, being then part of general dropsy. The function of the kidneys is rarely affected. Stomatitis, sometimes ulcerating, results from the lymphoid growth in the mucous membrane; and a similar change in the stomach causes interference with digestion and vomiting—symptoms which are increased by the anemia. Slight dyspnoea results from the blood-state, while intense difficulty of breathing, and even actual suffocation, may occur from the pressure of enlarged glands on the trachea or bronchi. The function of the

nervous system are variously deranged by the ill-nourished blood. Towards the end there may be convulsions, delirium, and coma. Pyrexia is a frequent, but not invariable symptom. It is almost always present in early life, much less common at advanced ages. The temperature may be considerably raised, even when the glandular enlargement is slight; the elevation varies from two to six degrees, and may be continuous, or with daily remissions, or periods of considerable elevation may alternate with periods in which it is only slightly raised.

COMPLICATIONS.—The pressure-effects of the enlarged glands, already mentioned, are sometimes so considerable as to give rise to complications, as thrombosis in vessels, pleural and pericardial effusions, and bronzing of the skin from disease of the solar plexus. Inter-current affections, occasionally met with, are Bright's disease, pneumonia, fatty degeneration of the heart and liver, erysipelas, pemphigus, boils, and other effects.

COURSE AND DURATION.—The disease may remain local for a long time, even years, affecting one group of glands only, and subsequently slowly becoming general. When the general enlargement of glands is established, the disease rarely lasts more than two years. It usually terminates fatally by anæmia; but not rarely by some secondary effect of the morbid process, as apoplexy, starvation, diarrhoea; or by a complication, especially by pneumonia.

PATHOLOGY.—The changes in the glands in lymphadenoma resemble, in the early stage, those which result from simple irritation; and, as has been seen, the first enlargement often appears to be excited by local irritation. Clinically, however, the disease has a semi-malignant aspect. Dr. Wilks therefore assigned to it a position between cancer and tubercle. Its history suggests that it is due to both constitutional and local causes, and that the extent of these two elements varies in different cases. The constitutional predisposition apparently affects chiefly the lymphatic structures. The assumption of such a predisposition is necessary to explain the general affection of the glands which characterises some cases in the beginning, and also the persistence of the affection when it begins locally, as well as its subsequent extension. In the latter case, however, a process of secondary infection may be at work, the lymphatic tissues, already predisposed, becoming affected by the circulation in the blood of a *materies morbi* derived from the structures first diseased. Some cases present characters intermediate between lymphadenoma and scrofula—the low tissue-vitality of the latter leading to wide fatty degeneration and cessation of the new growth, instead of its fibroid transformation. The existence of an excess of white corpuscles in the blood does not present valid ground for separating certain cases from the rest, and calling them 'lymphatic leucocythæmia.' Most of such cases are, as has been said, forms of mixed disease. In simple lymphadenoma the Malpighian follicles of the spleen are diseased, and when there is a considerable excess of leucocytes in the blood, the splenic pulp is usually also increased in quantity. The anatomical

lesions of splenic leucocythæmia and lymphadenoma are conjoined, and to the increase in the pulp the leucocytic excess is due. Occasionally, however, when the diseased glands are soft, lymphoid corpuscles, changed in character, pass from them into the blood, and persist there, leading to an excess of the pale cells. When the glands are hard, the production of lymphoid cells, and their passage into the blood, seem interfered with, and thus simple anæmia results.

DIAGNOSIS.—Local glandular growths cannot be sharply separated from cases of generalised lymphadenoma, although they may be clinically distinguished. Generalisation may ultimately occur, even though one group of glands has alone been diseased for many years. In splenic leucocythæmia the glands are only affected late in the disease, after considerable enlargement of the spleen has existed alone for a long time. When the spleen presents great enlargement, and the glands are affected early, the case is usually of the mixed form above described, both splenic pulp and follicles being diseased. In scrofulous enlargement of the glands, the disease is commonly confined to a single group of glands which have been subjected to local irritation; some of the glands often soften and suppurate; the affection occurs chiefly in early life, and the other constitutional signs of scrofula are present. Cancer of the glands differs widely in its microscopical characters from lymphadenoma, but clinically the distinction from a local lymphoma may be difficult, and turns chiefly on the slow extension of cancer to neighbouring glands, and in its subsequent localisation in organs rather than in lymphatic structures.

PROGNOSIS.—When the disease is widely spread, or the local growths considerable in size, a fatal termination is almost certain. The duration, however, in each case, varies much. The younger the patient, the better the preceding health, the longer is the duration of the disease. The consistence of the glands has little prognostic value. The softer they are, the more rapid is the course of the disease; but, on the other hand, if it is influenced by remedial agents, the soft glands can be restored to a better functional condition than the hard. The prognosis is worse the more profound the anæmia. Elevation of temperature as a rule indicates a rapid course, but to this there are some striking exceptions, as in one case under the writer's care, in which the glandular enlargement continued slight, although the temperature for twelve months was always above the normal.

TREATMENT.—The possibly infecting influence of the primary glandular enlargements has led to their extirpation. Where other glands, or the spleen, has been enlarged, the operation has done no good; and, in such cases, surgical interference is only justified by impending death from the local pressure. But where the affection has been confined to one group of glands, the progress of the disease has been retarded by their removal, and in some cases, the malady has even been cured. The degree of anæmia is of great importance as influencing the prospect of benefit, and even of survival from the operation, and the actual proportion of corpuscles should, in all cases, be estimated by the hæmacy-

seometer. An operation should never be performed if the proportion of red corpuscles is less than 60 per cent. of the normal. A slight excess of white corpuscles does not militate against the success of an operation. Other methods of local treatment have been employed, with some benefit, especially rubbing and sham-pooing, the alternate application of heat and cold, compression, and blistering. Galvanopuncture is useless. Various substances have been injected into the glands—iodine, nitrate of silver, carbolic acid, arsenic. The last has alone appeared useful (Winiwarter), but it was, in all cases, given internally at the same time. Of internal remedies arsenic is incomparably the most potent. It should be pushed to the largest doses the patient can bear, as mxx . of liquor arsenicalis three times daily. It often causes some pain in the glands, followed by their diminution in size, and even, in a few recorded cases, by their complete disappearance. Although such a favourable result has not come under the writer's personal observation, he has seen a marked diminution obtained in the size of glands which were before steadily enlarging, a diminution which has been maintained for years. Phosphorus has been given in the disease (first by Verneuil), but it is far less useful than arsenic. Iodine and iodide of potassium are of little service. Cod-liver oil is useful when there is any indication of a scrofulous diathesis. Mercury and carbolic acid have been given internally without success. Iron, useless alone, has sometimes appeared to do good when given in conjunction with other remedies. Change of air, general tonics, and careful diet are often of considerable service, especially when employed along with other measures. W. H. GOWEN.

LYMPHANGITIS (*ρίμφη*, water, or lymph, and *αγγίον*, a vessel).—Inflammation of lymphatic vessels. See LYMPHATIC SYSTEM, Diseases of.

LYMPHANGIECTASIS (*lymphe*, lymph, and *angiectasis*, vascular dilatation).—Lymphatic varix, or varicose dilatation of lymphatic vessels. See LYMPHATIC SYSTEM, Diseases of.

LYMPHATIC SYSTEM, Diseases of.—*Συκχ.*: *Fr. Maladies du Système Lymphatique*, *Ger. Krankheiten des Lymphsystems*.

There is no essential difference between the lymphatic and lacteal systems, which together constitute the absorbent system. In this article attention will be briefly directed to those diseases of the lymphatic vessels and glands which are more or less of a local nature; and what is stated with regard to the former will apply generally to the lacteals, but attention will be directed to any points connected with these vessels calling for special notice. Some of the affections involving these structures are considered in separate articles, and need, therefore, merely be mentioned here; while the mesenteric glands are discussed independently (see *MESENTERIC GLANDS, Diseases of*). It may be remarked that recent pathological investigations point to the existence of important relations between the absorbent system and certain diseases, namely, some of those belonging to the syphilitic class, and those depending upon septic

conditions, such as plague, typhus and typhoid fever, diphtheria, erysipelas, glanders, malignant pustule, snake-bite, dissection or post-mortem wounds, and certain forms of serous inflammation, such as puerperal peritonitis. Moreover, the lymphatic vessels seem to be materially affected in some skin-diseases, such as erythema and elephantiasis; while there are structures which consist mainly of lymphatic follicles, and their diseases principally affect these follicles. The absorbent system is also concerned in an important degree in conveying morbid products from one part of the body to another, such as cancerous elements, tubercle, or the syphilitic poison, and thus of disseminating these diseases through the system. These points are more fully dwelt upon in their appropriate articles, and now the individual diseases of the lymphatic system will be discussed in their appropriate order.

1. **Acute Inflammation.**—According to the structures involved, acute inflammation, connected with the lymphatic system, presents three varieties, namely:—(a) where the vessels are alone affected—*lymphangitis* or *angiolinitis*; (b) where the condition is limited to the glands—*adenitis*; or (c) where both vessels and glands are involved. It will be convenient to consider these varieties together. As a rule the disease is localised, but under certain circumstances the lymphatic system is more or less widely implicated, especially if the inflammation is of a septic character. It may be set up and extend with great rapidity.

ÆTIOLOGY AND PATHOLOGY.—The causes of acute inflammation of the lymphatic vessels or glands may be thus indicated:—1. *Traumatic*, including such injuries as wounds, contusions, or a severe strain. 2. *Irritation from without*. Strong heat, as that of the sun, may set up inflammation of the superficial lymphatics. Pressure or friction may also produce this effect upon the vessels or glands. It is not an uncommon practice to excite inflammation artificially in the glands, for the cure of certain of their diseases, by injecting irritants into their substance. 3. *Irritation from within*. This may be due to inflammation in the vicinity, suppuration, ulceration, diseases of joints or bones, and other causes. In medical practice the implication of the glands under the jaw, in cases of diphtheria and scarlatina, is a familiar illustration of this class of cases; or the inflammation of the glands behind the ear in cases of impetigo of the head. It may also be noticed here that the lymphatic vessels are more or less involved in phlegmasia dolens. 4. *Specific irritations*. These deserve separate recognition, and include syphilis, gonorrhoea, and various septic poisons, which frequently affect the lymphatic structures. Inflammation of the absorbent glands is also an important feature in plague, glanders, and other diseases.

With regard to the modes in which the inflammation is set up, this may happen in several ways. In the first place, the cause may act directly upon the lymphatic vessels or glands, as in the case of injury. Secondly, these structures may be involved by extension from neighbouring parts. Glands are frequently affected in this way; and lymphatic vessels may be

involved by continuous extension of irritation from inflamed organs, serous membranes, or other structures with which they are connected. Thirdly, the cause of the inflammation is often more or less remote from the situation in which it appears, especially in the case of the glands. This may arise from the condition passing continuously along the vessels from some seat of irritation to the glands in their course, or morbid products may be carried by the current of lymph to the glands, the vessels themselves being unaffected, when the inflammation thus set up is said to be *sympathetic*. In other instances pus has been found within the lymphatic vessels, having made its way from some seat of inflammation. It may also be mentioned that lymphatic inflammation may originate a similar condition in other structures, such as the joints, and this may be of a purulent character.

Inflammation is much more readily excited in the lymphatic structures in some persons than in others, and especially in those who are of a strumous habit. The glands are more liable to be affected in the early periods of life. A low state of the general health may predispose to inflammation of these structures from slight causes. Glands which are chronically enlarged, as the result of inflammation, are very liable to become the seat of acute inflammation from slight causes.

ANATOMICAL CHARACTERS.—Inflammation affecting the lymphatic vessels presents two forms, but they may be met with together. When the minute capillary network is involved, the condition is termed *reticular lymphangitis*, the skin and its capillaries are generally affected at the same time, so that there is more or less diffused redness, but it may present a reticulated arrangement. *Tubular lymphangitis* signifies that the main vessels are implicated. They are visible on the surface as red lines, straight or wavy, passing to the glands. They become dilated, and their walls thickened. Their internal coat is opaque and uneven, and the endothelium often disappears. Coagulation of the lymph within the vessels takes place, closing up their channel. The coagulum may become organised, so that they are permanently obliterated; or it may soften and even suppurate at the centre, and the products may enter into the general circulation, and thus cause septicæmia or pyæmia. The inflammation is liable to extend to the surrounding cellular tissue, leading to exudation, hyperplasia of cells, and consequent swelling and thickening.

Inflammation of lymphatic glands is characterised in the early stage by swelling, congestion, and increased firmness. The lymph accumulates, exudation takes place, and abundant cells are present. The inflammatory process may soon subside, terminating in resolution. In many cases, however, suppuration ensues, especially in certain forms of inflammation, this commencing in the centre of the glands, the cavities of which become more or less speedily filled with pus. The inflammation spreads to the surrounding cellular tissue, and, an abscess being formed, the pus makes its way to the surface. If the glands are internal, they may burst there, and lead to serious consequences; or by

merely setting up irritation in adjacent structures, they may produce similar results. Sometimes the glands remain permanently enlarged and indurated, especially after repeated attacks of inflammation, and they may become adherent to the parts around. A single gland may be inflamed, but it is common for a cluster or a chain of glands to be involved. In some cases the inflammation assumes a more or less sub-acute character, and the progress of events is slower.

SYMPTOMS.—These are *local* and *general*. The local phenomena consist of subjective sensations, and objective signs. Pain is felt at the seat of inflammation, which may be very severe, often accompanied with a sense of heat or burning, and stiffness or tension. There is usually marked tenderness, and this may be present when little or no spontaneous pain is complained of, while it is often remarkably limited to the use of an affected lymphatic vessel. Movement also increases the pain. The subjective sensations are more severe as a rule when the glands are involved. When suppuration takes place, the pain tends to assume a shooting and throbbing character. As regards objective signs, inflamed lymphatic vessels, if superficial, are usually visible as red lines, either straight or wavy, running in the direction of the glands, or there may be separate red patches. Should they be deeply situated, however, the vessels cannot be seen. The larger trunks may be felt by the fingers being cord-like, firm and knotted. The surrounding tissues are seen and felt to be more or less swollen and indurated. If the circulation of the lymph is much interfered with, a limb may be considerably enlarged, and presents a feeling of firmness and solidity, owing to the occurrence of lymphatic œdema.

When the lymphatic glands become inflamed, their enlargement can be detected, and the surrounding tissues may also be swollen. At first they feel firm, but if suppuration takes place they become more and more soft, and at last present a sensation of fluctuation. The overlying skin is markedly red, and there is often subcutaneous œdema. Suppurative inflammation of lymphatic glands constitutes the condition known as 'bubo.' If not opened artificially, the abscess ultimately bursts externally, but it may burrow considerably before doing so, and the opening is often imperfect. See Bubo.

The *general* symptoms accompanying inflammation of the lymphatic structures vary in their intensity in different cases, according to its severity, extent, and results. In the slighter cases there is no obvious constitutional disturbance. As a rule, however, more or less fever, with its accompanying symptoms, sets in, preceded often by shivering or even distinct rigors. If suppuration occurs the rigors may be repeated, the pyrexia increases, and more or less wasting follows, if there should be prolonged discharge of pus. Where the inflammation is of a septic character from the first, or when septic matters are conveyed into the circulation, the general symptoms are exceedingly grave, being similar to those indicative of septicæmia from other causes, such as repeated rigors, high and erratic fever, great weakness and prostration, low nervous symptoms, weak and rapid cardiac action and

pulse, and other typhoid phenomena. The termination is then usually fatal.

TREATMENT.—In the management of any acute inflammation affecting the lymphatic vessels or glands the first indication is to get rid of its cause, if this be practicable. In the next place rest is of essential importance, and the affected part should be so placed as to avoid all pressure or tension. As regards *local* treatment, the application of heat and moisture, by means of fomentations and poultices, usually answers best. To these anodynes may be added, if necessary, especially belladonna, and the latter may be often applied with advantage in the form of extract, mixed with glycerine. It is not uncommonly advisable to take away blood locally from the neighbourhood of inflamed glands, by means of leeches. Some authorities maintain that suppuration may sometimes be prevented by counter-irritation around the glands, effected by applying blistering-fluid or strong iodine. If suppuration take place, the progress of the pus towards the surface must be encouraged by the usual means, and the abscess opened at the appropriate time. Should *general* treatment be required, at first it is usually necessary to keep the patient on low diet, to open the bowels well, and perhaps to administer some simple saline mixture. When suppuration occurs, a more or less supporting tonic and stimulant treatment is called for. In some cases the free use of alcoholic stimulants, with the administration of full doses of quinine or salicine, constitutes the appropriate treatment.

2 Chronic Inflammation.—It is only the lymphatic glands which can be said to be liable to this affection—*chronic adenitis*. They may remain in a condition of chronic inflammation after one or more acute or sub-acute attacks, or this is set up as a chronic affection from some continued or repeated irritation. Formerly a low form of chronic inflammation was regarded as the primary lesion in scrofulous or tubercular glands and some pathologists still hold this view. The affected glands are enlarged and firm, and usually somewhat painful and tender. These changes may be due partly to a hyperplasia of the gland-structures, partly to an exudation into their midst. Frequently they continue in this condition for a long time, without undergoing any obvious change, but they are liable to acute exacerbations from slight causes. They may ultimately become the seat of caseous degeneration, or of suppuration even though there is no evident scrofulous diathesis. The circulation of the lymph through the involved glands is prevented to a greater or less degree. Usually there is no constitutional disturbance, unless a considerable number of glands are implicated, or they degenerate or suppurate.

TREATMENT.—It is not desirable to allow chronic adenitis to continue, as unpleasant or even serious consequences may ensue, and therefore it should be subjected to proper treatment without delay. Any source of irritation must be removed at the outset. Gentle friction over the enlarged glands, with some simple oleaginous or greasy material may be effectual in reducing them, or it may be necessary to rub in weak iodine ointment, or to paint the surface with

uncture of iodine. Counter-irritation by blisters may be sometimes useful. Internally cod-liver oil and quinine are frequently of much value, preparations of iron are also often very serviceable, especially the syrup of the iodide.

3. Scrofulous or Tubercular Disease.—The morbid condition of the lymphatic glands thus named may be conveniently discussed here, as the ultimate effects produced are very similar to those which result from chronic inflammation in certain cases. This affection, however, is supposed to be one of the manifestations of a particular diathesis—the *scrofulous* or *tubercular*—in which the absorbent glands are very prone to become the seat of certain changes of a destructive character. It will be discussed at greater length in other articles, and here it will suffice to offer a few general remarks on the subject.

ANATOMY.—Scrofulous disease of the glands often occurs in those who present obvious characteristics of the diathesis, but this is by no means always the case, for the subjects of the glandular affection may be apparently strong and healthy. Children and young persons are by far most frequently affected. The glandular changes may originally be set up by some irritation, which seems to give it a start, but in many instances there is no such obvious cause, and it appears to commence spontaneously. Once an absorbent gland becomes the seat of scrofulous changes, others in connection with it, or even at a distance, are very liable to become secondarily implicated.

ANATOMICAL CHARACTERS.—Scrofulous disease may involve the lacteal as well as the lymphatic glands, and of the latter those within the body may be affected, as well as those which are external. This disease of the lacteal glands is separately discussed (see *MESENTERIC GLANDS, DISEASES OF*), and also that of certain lymphatic glands within the chest (see *BRONCHIAL GLANDS, DISEASES OF*). Of the external glands, those in the neck and under the jaw are most commonly involved. The changes always go through a more or less chronic course. At first the glands become enlarged and firm, and, according to most observers, this seems to be merely due to a hyperplasia of the lymphatic elements. These, however, pass on but a very low degree of vitality, and have a marked tendency to degenerate and disintegrate, so that the tissues become destroyed. Ordinarily excision takes place, the substance of the glands becoming yellow and softened, then a slow process of unhealthy suppuration generally ensues, leading to the formation of chronic abscesses. The skin over them presents a congested appearance, and is often undermined for some distance, the subcutaneous tissues being involved in the suppurative process. If the abscesses are not properly opened, they are liable to cause much destruction of the skin, and to leave unhealthy sinuses and ulcers when they burst of their own accord. If they subsequently heal, this is often attended by extensive scarring, and the scars are permanent, but become less marked in course of time. In some cases the glands do not suppurate, but after excision they become calcified and inert; it appears that this result may take place even after the formation of pus, which then becomes inspissated, and mixed up with calcareous matter.

Symptoms.—In the case of the external glands, with which we are now concerned, the changes above described can be observed clinically. They are attended with little or no pain, but there is usually more or less tenderness. Constitutional symptoms are usually prominent, when the glands become to any extent the seat of scrofulous disease. There may be the symptoms of the diathesis; but the glandular affection itself also tends to produce wasting, anæmia, general weakness, and more or less pyrexia, which, if there should be abundant suppuration, is apt to assume a hectic type. If the glandular disease is limited, however, the system may suffer but little or not at all; and even after it has been extensive and severe, so as to lower the patient very much, recovery may take place under appropriate treatment, the patient ultimately becoming strong and robust. When the internal glands are affected, they may give rise to symptoms from their mere mechanical presence, such as those indicative of pressure or irritation, and if destructive changes occur in them, very serious results are liable to be produced. The general symptoms are also usually more marked in these cases, and may become extreme in degree. It must be remarked that it is highly probable that phthisis may be set up by an infective process, in connection with suppurating or caseous scrofulous glands.

Treatment.—General treatment is of essential consequence in the treatment of scrofulous disease of glands. The patient should be placed under the most satisfactory sanitary conditions that can be obtained; but in many cases this is a very difficult matter, and it is of great importance, if possible, to remove from their unhealthy and often wretched homes those suffering from this affection, and to treat them in suitable sanatoriums or hospitals. They should be as much as possible in the open air, and a change of air will often prove of decided benefit to those suffering from scrofulous glands. Residence at the seaside, with sea-bathing, is also of much service, or a sea voyage may be desirable. The digestive functions require careful attention and regulation; and the food must be nutritious, including abundance of good milk, fresh eggs, and such articles of diet. As regards medicines, those which are usually indicated are cod-liver oil, quinine, and preparations of iron, especially the syrup of the iodide, steel-wine, or Ferris's syrup. Where there is much suppuration, marked benefit has been found to result from the administration of minute doses of sulphide of calcium, and from chloride of calcium.

Local treatment is usually called for. In the early stages attempts may be made to cause absorption of the enlarged glands, but these must be cautiously conducted. Gentle friction, the application of preparations containing iodine or certain iodides, and the use of poultices or fomentation of sea-weeds, are the measures usually adopted. In some cases it certainly seems the best plan of treatment to try to encourage suppuration in glands which are in a torpid state, and which cannot be absorbed. For this purpose they have been injected with irritants. Suppuration and its consequences must be treated on ordinary principles; but it should be remarked that abscesses should not be allowed to burst of

their own accord, but need surgical interference, as otherwise they may lead to much destruction of the skin and subcutaneous tissues.

4. Hypertrophy and Atrophy of Glands.

The lymphatic glands become *hypertrophied* under different circumstances. In some cases there is a mere local hypertrophy, which shows no tendency to progress towards other parts, and which may be due to some obvious irritation, or independent of any known cause. As has been already pointed out, hypertrophy is the early condition of scrofulous glands. This morbid change is most important, however, in connection with the disease termed *lymphadenoma*, or *Hodgkin's disease*, in which there is a progressive enlargement of the lymphatic glands, and with one form of *leucocythæmia*. These affections are discussed in separate articles. Without entering upon any lengthy description, therefore, it will suffice to remark that in these affections the enlargement varies much in degree and extent in different cases, that it is due simply to an increase of the normal lymphatic structures; and that the glands usually show no tendency towards any degenerative or destructive change. Clinically they are recognised by their obvious physical characters when superficial, or by physical signs when situated in internal cavities. As a rule they are painless; but may give rise to various symptoms by their mechanical pressure, irritation, or destructive effects. In many cases more or less severe general symptoms are present. See *LEUCOCYTHÆMIA*, and *LYMPHADENOMA*.

Atrophy of lymphatic glands may occur after inflammation, as a senile change, after the removal of a limb, or its long-continued want of use, or from other causes. No definite effects can be referred to this condition, but if there should be extensive glandular atrophy it might obviously interfere with the due nutrition of the blood and general system.

5. Morbid Formations and Deposits in Glands.—Under this heading the following may be considered:—

a. Cancer.—The various forms of malignant growth frequently involve lymphatic glands. In most cases the disease is secondary to cancer in some neighbouring part, and the glands are very prone to become involved, owing to the cancer-elements being directly conveyed to them by the lymphatics. This is well exemplified by the implication of the axillary glands when the breast is the seat of cancer. Not uncommonly, however, the formation is primary in the glands, and then involves other structures by direct extension or convection. All forms of malignant disease are met with, but the encephaloid variety is most common. When secondary, however, it generally approximates in characters to the primary formation, and hence may be of a scirrhous or melanotic nature. It may also be mentioned here that secondary sarcoma occurs in the lymphatic glands. The growth may attain a considerable size, and it is more or less nodulated. The consistence will depend on the variety of the cancer, often it is soft, and a milky juice escapes on pressure. If cancerous glands are external, they can be recognised on examination, and are usually painful and tender.

When situated internally they give rise to physical signs of their presence, either in the chest or the abdomen, and to more or less pressure-symptoms, which may be combined with the constitutional symptoms of malignant disease. It may be very difficult to distinguish clinically between cancerous glands and lymphadenomatous growths situated internally.

Albuminoid disease.—The glands are liable to be involved in conditions which give rise to albuminoid degeneration. On section they present the peculiar waxy, pale, translucent, homogeneous appearance characteristic of tissues which are the seat of this change. The glands may be enlarged, but when they attain a considerable size, this is partly due to hypertrophy. In other cases they are small and firm. This condition may give rise to symptoms by pressure, as sometimes happens in the case of albuminoid glands in the portal fissure, which may cause ascites or jaundice.

c. Pigmentation.—The bronchial glands may be the seat of a deposit of black particles in cases where the lungs are thus affected, as in miners, colliers, &c. They are enlarged to some extent, and black; and a black liquid escapes on pressure. This condition does not give rise to any obvious symptoms. More or less pigmentation of these glands is often observed with advancing age.

d. Syphilitic growths.—The glands in the groin are affected from the irritation of the primary syphilitic sore, and others are often involved in connection with its secondary and tertiary effects, but no doubt they are also liable to become the seat of special syphilitic formations.

e. Tubercle.—The condition of glands usually termed 'tuberculous' has been already considered, but sometimes distinct grey granulations are found in connection with acute tuberculous. They originate in the follicles of the glands.

TREATMENT.—Practically the treatment of the morbid formations in glands just considered if any be called for, consists in measures directed against the constitutional condition of which they are a manifestation. In the case of cancer, operative interference may be demanded. Symptoms, especially those resulting from pressure, may also require special treatment.

6. Chronic Changes affecting Lymphatics.—The lymphatic vessels are subject to two principal classes of chronic changes, namely (a) *Dilatation* and *hypertrophy*; and (b) *Obstruction*.

a. Dilatation and hypertrophy—Lymphangectasia.—Leaving out of consideration the thoracic duct and receptaculum chyli, the lymphatics, either superficial or deep, and also the lacteals, may become more or less dilated and hypertrophied. Even the vessels of internal mucous or serous membranes may be thus affected. In most cases the larger trunks are implicated, but the capillary plexuses are sometimes chiefly or alone involved. With regard to the causes of this condition, it is often congenital, and has then been attributed to a want of specialisation in the lymphatic system of certain parts. In other cases it is evidently due to some obstruction to the circulation of the lymph, and consequent enlargement of the vessels behind the impediment. Such ob-

struction may be seated in the glands or vessels, and in the latter case may be due to internal plugging or to external pressure. In some instances the enlargement of the lymphatics partakes of the character of a primary hypertrophy, either alone, or along with other tissues, as in connection with elephantiasis and other growths, of which enlarged lymphatics constitute an important element. Dilatation has been also attributed to a supposed paralysis of the muscular coat of the lymphatic vessels. Lymphangectasis is most common in warm and moist climates.

There are various forms which enlarged lymphatics assume. Thus, there may be simply a localised dilatation of the capillaries, constituting a visible freely-anastomosing reticulum or network. More commonly the trunks are enlarged, assuming a tubular, fusiform, varicose, aneurinal, or cirsoid form. Or a distinct growth may be produced, which has been specially termed *lymphangectasia*, and has been divided by Wagner into three varieties—(1) *simple*; (2) *cavernous*; (3) *cystoid*—names which sufficiently indicate their several peculiarities. The walls of the vessels are often more or less thickened from hypertrophy. Dilated lymphatics are liable ultimately to give way, with consequent escape of the lymph.

Clinically the conditions now under consideration are visible when superficial, or when occurring on a surface which can be inspected. The appearances will differ according to the particular morbid change present. There may be a distinct tumour; or the enlarged lymphatics may only form one element in certain growths. Cystic formations originating in the lymphatic system are said to be most common in connection with the upper lip, tongue, and neck. It is beyond the province of this article to describe these conditions in any detail. Enlargement of the superficial lymphatics is chiefly observed on the inner side of the thigh, the sides of the abdomen, and the scrotum and penis; they appear in the form of vesicles like grains of sago, grouped regularly or irregularly. Sometimes only ampullæ are formed, which are generally soft and painless. These conditions have been mistaken for hernia, abscess, scrofulous glands, and other diseases. Should the dilated lymphatics rupture subcutaneously, vesicles containing a clear or milky fluid appear. They may rupture on the surface of the skin, the lymph being discharged externally, which is an important element in the diagnosis of doubtful cases. When dilated absorbents are situated internally, they cannot be recognised unless they should happen to rupture, with the escape of their contents by some outlet. This applies mainly to the lacteals, the contents of which may pass out with the stools, and to the urinary mucous membrane, it being supposed by some pathologists that the condition termed *chyluria* is merely due to the rupture of dilated lymphatic vessels in this membrane.

b. Obstruction.—As in the case of dilatation, the capillary plexuses or larger lymphatics may be obstructed. This may arise chiefly from plugging of their channels by coagulated lymph; inflammation of the vessels; pressure by enlarged glands, aneurisms, or other tumours, or merely

as a result of inflammation of the cellular tissue around the vessels. It may be remarked here that lymphatic tissues, similar to those observed in the glands, sometimes form here and there in the course of the lymphatics in cases of lymphadenoma. The lymphatics of the urinary mucous membrane are also supposed by some pathologists to become the seat of aggregation of the animal parasites named *filariae*, and they consider that this is the cause of chyluria.

The effects liable to be produced by obstruction of lymphatic vessels are swelling, from so-called lymphatic oedema; and dilatation of the vessels behind the obstruction, which may lead to their rupture. It is by these effects alone that this condition can be recognised clinically.

TREATMENT.—But little can be done for the chronic changes now under consideration affecting lymphatic vessels. Proper bandaging, or the use of some elastic support, may be of use in treating dilated vessels, if they happen to be conveniently situated. Friction and kneading may assist in removing lymphatic oedema due to obstruction. Growths come under the treatment of the surgeon, and do not call for any special remark here.

LYMPHATIC TEMPERAMENT. See TEMPERAMENT.

LYMPHOMA—A synonym for lymphadenoma. See LYMPHADENOMA.

LYMPHOEREGHIA or **LYMPHORRHOEA** (*lymphæ*, lymph, from *λύω*, water, and *ρρῦμις*, I burst forth, or *ρῆς*, I flow).

DEFINITION.—These terms literally signify a flow of lymph, but they are used to indicate an abnormal discharge from any part of the absorbent system, whether it be of lymph or of chyle.

ÆTIOLOGY AND PATHOLOGY.—Lymphorrhagia may take place from the lymphatic capillaries or trunks, from the lacteals; from the absorbent glands; or from the receptaculum chyli or thoracic duct. Cases in which this condition occurs are usually divided into *traumatic* and *idiopathic*, according to their apparent causation. In the former the cause is a wound, which generally affects either the thoracic duct, the larger lymphatic trunks, or the glands. A discharge of lymph has in rare instances followed even a slight wound, particularly in the neighbourhood of joints, and this was attributed by the late Mr. Monro to a constitutional defect—a *lymphorrhagic diathesis*, corresponding to the hæmorrhagic diathesis. *Idiopathic* lymphorrhœa is almost always the result of dilatation of a vessel or vessels, which ultimately rupture. They are often greatly distended before they give way. Allusion may again be made here to the supposed relation of chyluria to the presence of *filariae* in the lymphatic vessels of the urinary organs, these

parasites causing them to rupture, and the lymph consequently being discharged with the urine.

SYMPTOMS AND EFFECTS.—Should an escape of lymph take place upon any part of the surface of the body, it differs much in its quantity and characters in different cases. It may be less than an ounce or amount to five and even ten pounds within the twenty-four hours; while in the same case its quantity is liable to vary from time to time, and the flow has even been known to assume a periodic character, increasing during the period of digestion. In traumatic cases the discharge either presents the ordinary appearance of lymph, being clear and limpid, or it is mixed more or less with blood or with inflammatory products. When rupture takes place spontaneously after dilatation of the vessels, the fluid is more like chyle, being more or less milky and white, from the presence of particles of fat, but its characters are liable to alter from time to time. It contains a variable quantity of fibrinogenous elements, and is proportionately disposed to coagulate spontaneously. Internal lymphorrhagia causes different results. In the case of the intestines and urinary organs, the fluid is discharged with the feces and urine respectively, in the former case being supposed to give rise to fatty stools, and in the latter to chyluria. The late Mr. Bradley attributed some cases of effusion into serous cavities, such as certain forms of hydrocele, hydrocephalus, pleuritic effusion, and ascites, to a lymphorrhagia into the respective cavities, and the writer has met with a case of ascites which seemed to support this view. Fatal peritonitis has resulted from the entrance of chyle into the peritoneum, owing to the rupture of a dilated receptaculum chyli. The escape of lymph or chyle out of the system tends to affect the general health, and if it is in large amount, this is likely to lead to marked emaciation, debility, and anaemia.

TREATMENT.—In external lymphorrhagia all that can be done is to check the flow of lymph by pressure of bandages, and the application of astringents. In cases where it takes place into internal passages, the use of iron in full doses may be of service. The general condition must be attended to, and improved by nutrients and tonics, if required.
